From the study of syringomyelia, a disease affecting primarily the central gray matter, and having for its most distinctive clinical manifestation a dissociated anæsthesia, the gray matter of the spinal cord has come to be regarded as intimately connected with the passage brainward of the sensations of temperature and of pain; and it is further probable that, whatever may be the paths for the sensations of touch, they are not in the gray matter. We expect, therefore, that in all cases, whether chronic or acute, in which the lesion is confined to the structures surrounding the central canal, the ability to recognize thermic and painful stimuli will be impaired or lost, while tactile sensibility remains normal. Such is the condition in focal hæmatomyelia. Sensibility is not affected, but there exists thermo-anæsthesia or analgesia, or both together. It is generally necessary to examine these functions specifically, as the patient will say that he "feels everything," being unaware that he cannot tell heat from cold or feel pain. The distribution of these disturbances is in general the same as that for the total anæsthesia of transverse lesions. The Brown-Séquard type is often seen, viz., a motor paralysis of one arm and leg, with loss of pain sense and temperature sense in the opposite side. The degree of thermo-anæsthesia and analgesia is not constant. As a rule, analgesia is the less of the two; in recovery also, it is the first to improve or disappear. From personal experience I can speak only of the loss of temperature sense. That has generally been, for the first few weeks after the accident, complete, so that the patients were not only unable to distinguish between heat and cold, but felt no discomfort from contact with the test tube of boiling water, although other kinds of painful stimuli were appreciated at their true value. When the symptom was incomplete at first, or when time had permitted it to become so, it appeared as a delayed perception. The tendency of these affections of the pain and temperature sense is toward improvement, and sometimes recovery is perfect.

The other symptoms of these large focal hemorrhages are those of spinal-cord injuries generally. Thus, there may be pain, loss of sphincter control, bedsores, priapism, œdema, cyanosis of the extremities, etc. In purely hemorrhagic conditions, however, these are generally characterized by their short duration and by one or more of them being absent. The chief title to distinction which these cases possess is their relatively good prognosis. Many of the patients recover almost entirely. It is certainly remarkable to see a man who had been completely paralyzed in all four extremities as the result of a severe injury, walking about again and pursuing a gainful occupation. It has been my privilege to see this in several cases, and there are numerous examples of it in literature. In the earlier article I described such recoveries in detail. Since that writing the following case has come to my observation:

A man, thirty-one years of age, fell off a cart, striking on the right side of the head, on July 21, 1899. He was immediately paralyzed in both arms and in the left leg, and for three days following there was retention of urine. On September 6th, less than eight weeks after the accident, when examined at the Vanderbilt Clinic, the right arm had nearly entirely recovered; the left arm was still weak, as was the left leg, though the patient could walk without much difficulty. There was no deformity of the vertebræ, though the movement of the neck caused pain. Tactile sensibility was everywhere normal, but there remained considerable impairment of thermal and pain sensibility in the right side of the body, *i.e.*, on the side opposite to the motor palsy, thus constituting the Brown-Séquard type. Thus, in less than eight weeks after an accident which had caused complete paralysis in three members, one arm had recovered almost entirely, the other arm was useful to a certain extent, and the paralyzed leg had regained sufficient power to make locomotion easy.

B. Small Focal Hemorrhages: It is evidently impossible to distinguish sharply between large hemorrhages and small ones; the one merges naturally and imperceptibly into the others. But as there are many clinical cases of hæmatomyelia of which it is possible to say that the hemorrhage and consequent injury to the cord are extensive—so are there others in which it is equally possible to assert that the hemorrhage and cord injury are minute. Under "Large Focal Hemorrhages" were described the cases in which the initial paralysis was extensive, involving three or more of the extremities, and associated, at first at least, with many other evidences of severe lesion. Under "Small Focal Hemorrhages" an account will now be given of the cases in which many of the cardinal symptoms of injury to the spinal cord will be sought for in vain, and in which such symptoms as are present are incomplete or limited in distribution. These small hemorrhages rarely if ever cause death, and consequently post-mortem evidence concerning them is meagre. But they are occasionally found after death in the bodies of persons dead from other causes; and there are many correlated facts which make diagnosis reasonably certain. Chief among these are the facts that the symptoms point to the cervical region, and that they indicate in their mode of origin, their individual characters, and evolution, a central lesion of the cord.

It has been thoroughly demonstrated that the cervical region is the elective seat, if not the exclusive one, of primary focal hæmatomyelia. It is the region of which our knowledge of fibre courses and cell groups is most complete. It is here that such diseases as syringomyelia and progressive muscular atrophy, which have furnished invaluable information as to spinal-cord structure and function, have their favorite starting-points. From the fourth cervical through the first thoracic segment are grouped the muscle nuclei for the upper extremities; the sensory supply, in sharply differentiated areas, of the whole integument below the neck; the cilio-spinal centre, and various centres of reflex action. The functions of this region are so important and so closely packed together, and their allocation is so well known, that even a slight lesion can hardly pass undetected and unlocalized. Such a minute lesion is exemplified in the following case:

The patient, a man forty-three years of age, with an unimportant previous history, was injured in an elevator shaft on November 11, 1898. He was packing the cylinder, and was wedged in between it, the wall of the elevator shaft, and a discharge pipe, when the balance weight of another elevator came down slowly, engaging his head on the left and back surfaces. Being unable to extricate himself, and the weight continuing to descend slowly, his head was bent forward and to the left on his chest, and in this position he was pressed down to the floor. This is all he remembers of the accident. When he recovered consciousness, about two hours later, he was in the New York Hospital. His symptoms then were: Laceration of the scalp, where the weights had pressed; severe pain and tenderness in the neck, with limitation of movement; tingling in the tips of the fingers of both hands. He could move all the extremities freely, although they felt weak; he could pass his water normally; his bowels moved regularly. He remained in the hospital for two weeks, the treatment being directed to the stiffness and pain in the neck and to the scalp wounds. He had no bed sores. When discharged from the hospital the pain in the neck was still troublesome, and he felt weak generally, conditions which have been gradually improving.

FIG. 8.—Diagrammatic Representation of the Anæsthesia and the Condition of Reflex Activity, in a case of primary focal hæmatomyelia from injury.

Examination, January 24, 1899, Vanderbilt Clinic: The patient is a fairly well-nourished man. There are no disturbances of mental capacity, no interference with the special sense functions of sight, hearing, smell, or taste. The pupils are normal. There are no symptoms referable to the cranial nerves. The neck is held somewhat forward on the chest and is very stiff. Attempts to cause movement in it in forward, backward, lateral or rotary directions, either on the part of the patient or of the examiner, cause sharp pain. There are, however, no demonstrable evidences of fracture or dislocation in the vertebræ. The only positive indications of destructive lesion in the nervous system consist in a patch of anæsthesia over the right shoulder and a foot clonus on the left side. The anæsthesia, as indicated in the diagram (Fig. 8) corresponds to the deltoid region. In the area marked black on the chart it is profound and total, so that touches are not felt, pin pricks cause no pain, and temperature sense is abolished. Surrounding this patch of total anæsthesia in front, behind, and above, there is a narrow zone of diminished sensibility, which merges into normally sensitive skin. Below, the whole right arm is not so acutely sensitive as the left, although there is no objective anæsthesia. In the trunk and legs feeling is the same on the two sides. The foot clonus on the left side is rhythmic and fairly forcible. It is not particularly persistent and is easily exhausted. The tendon reflexes are everywhere very lively. The left knee-jerk is more active than the right; elsewhere there is little comparative difference between the tendon reflexes of the two sides. The man is weak generally, but he is not conscious of, nor was I able to demonstrate, a greater weakness on one side than on the other. Fibrillary twitchings manifest themselves upon use of the muscles of the upper extremities. They seem equal on the two sides. There is no atrophy. The measurement of the limbs of the left side are somewhat less than those of the right, but not beyond physiological limits. There have never been rectal or vesical difficulties.

This is evidently the history of a case of spinal-cord injury. Yet many symptoms, usually prominent, were at no time present. There was no paralysis of motion; the sphincters acted physiologically; there were no trophic disturbances. The lesion therefore must be very minute. The diagnosis of hæmatomyelia is based upon the character of the accident, the anæsthesia, and the condition of the tendon reflexes. The accident caused a forced flexion of the neck, the most fertile cause of intramedullary bleeding; the anæsthesia, since it involved all forms of sensibility, is best explained by a lesion in the dorsal half of the left dorsal horn; and a lesion there, since it would press most severely upon the left (crossed) pyramidal tract, would account for the excess of knee jerk and foot clonus on the left side. All the symptoms can be harmonized by assuming a lesion within the cord, and by that only. And as hemorrhage is the chief primary intramedullary lesion from traumatism, there can be little question that a focal point of bleeding in the left posterior horn, extending not above the fifth cervical segment, is the correct explanation of this case.

Since a focal hemorrhage may vary greatly in situation and in extent, and since small hemorrhages may be multiple, it is evidently impossible to create any sharply defined symptomatological category into which all cases may be gathered. The lesions being small, there is a still further departure from the clinical picture of a transverse lesion than in the large focal hemorrhages. There is usually no loss of rectal control, and the bladder, if involved at all, is so only temporarily. Bed sores, as the patient is rarely confined to bed for a long time, do not occur. Sensory symptoms, with the exception of pain, may be entirely absent. This is the case especially when other evidences point to implication of the ventral horn nuclei. Anæsthesia, if it exists, is not widespread. It may involve all forms of sensibility as in the case just cited, or may be of the dissociated type. The Brown-Séquard distribution is common. Pain is generally present to a greater or less degree. It may manifest itself simply as pain and stiffness in the neck, or it may take the form of "root pains," and be extremely severe. The paralysis of voluntary motion is similar to that described under large focal hemorrhages, viz., a paralysis with rapidly ensuing atrophy, some of which will be permanent, of the peripheral neuron type, in one or both upper extremities; and, if the pyramidal tracts are encroached upon, a spastic weakness of one or both legs. In small hemorrhages the knee jerks are usually lively or exaggerated from the outset. This is an important differential sign from large hemorrhages. The symptoms referable to lesion of the cilio-spinal centre are usually limited to a myosis, often unilateral. Fibrillary twitchings, so constant a sign in chronic disease of the motor nuclei, are no less frequent in acute lesions. In some cases of injury to the back a persistent fibrillation in one or more muscles of the shoulder girdle is the only evidence of spinal-cord involvement. In all cases it should be looked for. Occurring alone, or associated with other symptoms, it is of great diagnostic value. It is found especially in the pectoralis major, the triceps, and the biceps. It is more difficult of recognition in the compactedly placed muscles below the elbow.

The condition known as diplegia brachialis traumatica has usually been explained by assuming an extra-dural hemorrhage. In the absence of post-mortem evidence of the existence of such a lesion as an isolated condition, and in the light of our present knowledge of hæmatomyelia, it seems to me that the clinical condition must henceforth be recognized as resulting from hemorrhages into the cord and not outside it. The symptoms consist in a flaccid paralysis of both upper extremities appearing as the immediate result of an injury to the neck. The legs are not involved; there is generally no anæsthesia, and the sphincters are implicated slightly and temporarily or not at all. Pain may be prominent, but it may also be slight or absent. The knee jerks may be normal or hyperactive. The following from the Vanderbilt Clinic is a typical illustration of this condition:

A man, fifty-four years of age, was run into on the street by a light carriage on December 2, 1899. He was stunned for a moment or two, and is consequently unable to give the exact details of the accident. He thinks, however, that one of the shafts struck him in the neck from behind, and that then the carriage ran over him. As a result of this accident there were the following conditions: Fracture of two ribs, scalp wounds, and paralysis of both upper extremities. The patient went to Roosevelt Hospital and stayed in bed ten days. During that time he says there was complete paralysis in the shoulders and in the upper arms, and great weakness in the forearms and hands, though he could use these to a certain extent. The right side was more affected than the left. The neck was stiff and painful on movement, and there was severe pain between the shoulders and in the neck, which darted down the arms as far as the elbows. These latter darting pains caused the patient intense suffering. At no time was there any paralysis of the legs, of the bladder, or of the bowels; nor was the patient himself conscious of any impairment of cutaneous sensibility. There were no bed sores. On January 8th, the patient came to the Vanderbilt Clinic, when the following notes were taken as to his condition:

The patient is well built and well nourished, and walks naturally, though the head and neck are held rather stiff. There is a slight prominence of the seventh cervical spine, but no marked tenderness. The movements of the neck are fairly free and cause no pain. Both upper extremities are weak, and around the shoulders there is almost total paralysis. This latter affects the deltoid, the spinati, the rhomboids, and the supinatores longi. These muscles are pronouncedly atrophied, are the seats of fibrillary twitchings, and respond sluggishly to faradism. In the other muscles of the upper extremity the affection is weakness rather than paralysis, and evidences of degeneration of muscle tissue are wanting. The knee jerks are normal. It is impossible to demonstrate positively pathological disturbances of sensibility. Touch is everywhere normal. It may be that on the inner sides of the arms and over the chest sensibility to pain is less acute than it should be, and that in these regions the patient is somewhat uncertain in his recognition of heat and cold. These disturbances, if they are regarded as such, are too slight to warrant the terms of analgesia or thermo-anæsthesia. The symptoms, therefore, were almost purely motor and were confined to the upper extremities. It is evident that the pyramidal tracts for the legs were not destroyed nor pressed upon. A lesion able to cause such symptoms must affect the ventral horn nuclei, or the ventral nerve roots, without encroaching upon sensory tracts or the pyramidal tracts. How a hemorrhage situated without the cord could cause such selective symptoms it is difficult to see; neither does it seem probable that all the ventral roots going into the formation of the brachial plexus could be so seriously injured as to cause bilateral brachial palsy, without at the same time there being other conspicuous symptoms on the part both of the spinal cord and of the spinal column. In contrast to these improbable hypotheses is the one which postulates that the lesion consists of hemorrhage among the nuclei of the brachial nerves in the fourth cervical segment. This latter explains perfectly all the symptoms, and its correctness seems almost incontestable in view of the demonstrated frequency with which hemorrhage involves the gray matter of the cervical region.

As to the prognosis of these small focal hemorrhages, little is to be said. Life is not directly menaced by them. The degree of ultimate disability is dependent upon the situation and size of the hemorrhage. Like the larger hemorrhages, the initial paralysis is susceptible to a great degree of improvement. For example, an arm which at the outset was completely paralyzed, after a few weeks or months has regained its function in all but a few muscles or groups of muscles. Muscles in which atrophy sets in early and progresses rapidly are the least likely to regain full power. But even in them there may be considerable return of usefulness. The paralysis is the only symptom which need cause anxiety. Anæsthesia is usually transitory, and even if it persists it rarely causes any serious trouble.

The treatment of both large and small hemorrhages is to be conducted on the same lines. As the hemorrhages are within the cord, they are beyond the reach of surgical aid, and operation, therefore, becomes absurd. This will of course be granted by any one. But until surgeons generally become more familiar with the differential diagnosis of injuries to the spinal cord, cases of primary hæmatomyelia will continue to be operated upon. And the relatively favorable prognosis inherent to them will be turned to the embellishment of the fame of the operator.

Rest in bed is the first primary requisite for these cases. When the legs are paralyzed, there is of course no other alternative. Then a water-bed is necessary. But even when the patient can walk, he should be kept in bed for ten days or two weeks after the accident, or longer if necessary. Orthopædic appliances are not indicated. The customary attention to bowels and bladder should be carefully given. The pain in the neck can often be relieved by the use of the thermo-cautery, or analgesic drugs may be necessary. The iodide of potassium in ten-grain doses may have an effect in hastening the absorption of the blood clot. Faradism to the paralyzed muscles should be given as long as they react to it. If they fail to respond, galvanism is to be substituted. After the immediate effects of the injury have passed, massage and passive motion in the neck are useful.

Disseminated hemorrhage: There is little to be said concerning the clinical characteristics of primary disseminated hæmatomyelia, for we have no means of positively diagnosticating it during life. If, combined with the scattered blood extravasations, there is a point of bleeding in a functionally important region of the cord large enough to give focal symptoms, there will be the symptoms of focal hæmatomyelia plus the evidences of a general commotion of the cord. When, however, there is no single collection of blood cells large enough to interfere with the function of afferent or efferent tracts, of cell groups or of reflex arcs, in a way to permit a clinical recognition of local interference, the diagnosis, if it be attempted, can at best be only one of probability, depending upon the pathological possibility of disseminated hemorrhages, together with the general clinical evidences of shock.

It seems to be extremely probable that many of the vague yet persistent nervous disturbances which are occasionally seen after severe general traumatisms are the direct results of such hemorrhages.

SOME REMARKS ON THE TREATMENT OF SYPHILIS.

By CHARLES J. PROBEN, M.D.,

CLINICAL ASSISTANT TO THE CHAIR OF GYNÆCOLOGY, MEDICAL DEPARTMENT, COLUMBIA COLLEGE.

If comparison is invited with the class of ordinary infectious diseases, syphilis will be found to have many points in common. In fact, syphilis is regarded as an infectious disease, imparting its virulence from a local focus to the fluid tissues, producing constitutional symptoms, which abate and in their wake leave insidious constructive processes that ultimately degenerate and take on a destructive type. Practically a division of syphilis into primary, secondary, and tertiary stages is helpful in ascertaining pathological conditions and the resultant treatment, though such classification may appear rather arbitrary and fanciful. Rather a debatable question arises, why one person should present an apparent immunity to the syphilitic virus, while another may become severely infected by inoculation. No doubt good general health offers a certain check or a bulwark in counteracting the effect of this morbid infection. Susceptibility of the individual probably depends upon the inherent vulnerability and the resistant power of the tissues of the healthy body. And the better the health appears, the more reasonable would it seem that the tissues and the circulating fluids should counteract this unknown poison. Hence no two bodies exhibit the same degree of virulence, and no two bodies present the same fortifying and repelling influences of their tissues. Whether the disputed germ of syphilis or its resultant ptomains are responsible for the prolific cell growth in lues I am not prepared to state. This luxuriant cell growth readily and vigorously attaches itself to the walls of the lymph- and the blood-vessels, and so induces many morbid tissue changes. It is surmised that this almost explosive cell distribution throughout the body wages constant war against the tissues, the cells finally implanting themselves upon some vulnerable point, producing morbid processes extending over a number of decades, or even over the lifetime of the individual. Manifestations may appear at any time without warning; in fact, in the course of time they become more alarming and destructive, finally leaving irremediable sequelæ. Implantation of syphilitic processes acts at first destructively upon the functions of the organs, later sapping their very vitality.

The morbid tissue of syphilis is of a granulation type and has certain characteristics to distinguish it from other types of tissue. Granulomata are apt to infiltrate the lymph-vessels and nodes and the walls of the blood-vessels, being accumulative primarily, but owing to poor vascularization they readily undergo destructive metamorphosis. This tissue has characteristics in common with other tissue, in that it is subject to attacks of inflammation, suppuration, and caseation, yet it is a notable and a characteristic fact that even large accumulations of syphilitic granulation tissue become entirely dissipated by vigorous antisyphilitic medication. This capacity for complete absorption and disappearance without leaving any marks of ulceration or degeneration may be caused by various factors, but it strikes me that it is the only morbid tissue which will positively yield to medicinal treatment. The ravages of the disease increase with age, though it might be supposed that the germicidal effect of the blood plasma would be antagonistic to syphilitic infection, and so wear out its virulence. There is a constant effort of one trying to conquer the other, health having the germicidal action of the tissues in its favor. Our gratitude is due to the natural processes of our fluids, which are usually victorious; for experience teaches that in years elimination of the infection takes places in over two-thirds of those afflicted, who fail to record any but primary and secondary manifestations of this dreaded monster. In other words, we may put it as an axiom that over sixty-five per cent. of the afflicted escape tertiary manifestations or sequelæ, the foe being conquered by the elements of time and good health. Prolific cell hyperplasia at first gives rise to indurations; steady accumulations give rise to swellings and tumors. Progressive plastic elements increase the thickness of the walls of the blood-vessels, obliteration of their lumina may ensue, with thrombosis and embolism and a cut-off blood supply. For a vital organ like the cerebrum we see how important and necessary a good supply is—far more so than for the spinal cord. As a sequela a subsequent destruction of tissue takes place; the function at this area is forever destroyed, and it would not be feasible to suppose that this softening could ever be completely regenerated. This is one of the destructive ravages of this dread disease, and while we cannot regenerate what is completely destroyed, we may hope to check the progress of a contiguous and similar process which has not so far advanced. Suppose pressure of a similar growth upon the delicate nerve fibre produces a descending nerve degeneration with entire disappearance of axis cylinder and replacement of connective tissue, would we expect the connective-tissue changes to disappear completely, after their existence for a long time has caused the nerve to cease functionating? No, undoubtedly not, though we are aware of the great reparative power of nerve fibres, especially if peripherally injured. You say, What has all this to do with syphilis? A great deal, I say, because many of us expect to cure all kinds of lesions if they are syphilitic in character; we do not consider that they are sequelæ, which fail to respond to treatment, though they may have been caused by syphilis. Especially does this argument hold good in various cerebral affections of an organic type, excluding functional and nutritional diseases, in which syphilis plays a very important rôle as a causative factor—in fact, the most important, excluding heredity, worry, excitement, alcohol, etc. Nerves are far more prone to become regenerated, but they never can replace connective-tissue changes; restoration is as impossible in descending degenerations as it is impossible to restore cerebral softening when function has once become lost. In these lesions we must not expect too much from treatment, though we may be able to inhibit a further extension of the disease. There is no relation between a primary focus of infection, which may be very minute, and later manifestations, which may appear very severe and destructive. As a rule, from the local focus of infection we have little to fear; it is the harbinger of an already infected system, which may be followed by syphilodermata and a febrile movement. The multiform eruption of the skin need give us less apprehension than the visceral complications, which are apt to appear later, affecting the functions seriously and inducing structural lesions. These remarks apply generally, except to those cases dreaded so much, though fortunately rare, the cases of galloping syphilis. The mooted question, whether tentative excision of the local infection should be practised in order to induce a more favorable and attenuated disease, can be readily dismissed with the answer that extirpation is rarely practised, though it may appear to hold out hopes of lessening the virulence of this noxious poison. It is well known that the cure of the focus is a simple matter, unless a mixed infection causes much suppuration, when radical means must be resorted to. Excision to-day is very much discredited, as infection readily extends and permeates the tissues with wonderful rapidity. Enlargement of lymphatic vessels and general adenopathy, especially inguinal, and the syphiloderma, usher in the second stage. If the initial lesion is a doubtful one, it is a much-disputed question whether to begin treatment at once or wait for secondary manifestations. In order to give weight to our diagnosis and to strengthen our belief, it is better to wait until constitutional evidences arise rather than subject the victim to tentative treatment which is productive of nothing but leads us into error, not only for a short time but for a number of years, when we may regret to have before us an example of disease of a questionable character. The appearance of objective signs, taken in conjunction with an initial infection which was of a dubious character, will give a picture that removes all future ambiguity as to the character of the treatment to pursue. Great injustice may be done the patient in suspending over him a constant cloud of condemnation, whenever a symptom arises that cannot be explained, and that with great trepidation will surely be ascribed to the causative influence of syphilis. Syphilitic virus tenaciously lurks in the organism and insidiously affects the viscera and the osseous system, gradually producing serious lesions, the more rebellious to treatment the longer the process has continued.

Allusion has already been made to the resistant and overpowering action of the healthy tissues of the economy, and the possibility of a successful combat of the normal tissues with the specific poison, gradually attenuating the virus and rendering it innocuous, till at last they gain a decided victory over their weakened foe, that finds no further nidus for implantation and finally succumbs. Whatever be the character of the poison or its composition, though not an entity, it is apparently never dormant, always eager to prey upon weakened tissues, and this will explain why tissues debilitated by constitutional vices, dissipation, and alcoholic excesses succumb readily. Hence it is of the utmost importance in the treatment of syphilis to have a patient in as good a physical condition as we may possibly secure. Some of the worst cases of tertiary syphilis we see in those who in their youth have wilfully abused their constitutions, and who appear not well able to cope with the inroads of disease.

Medicinal treatment of syphilis by mercurial salts has been well known for centuries. In fact, these salts have been eminently successful in the primary stages; but the same cannot be said of iodide of potassium, though it appears absolutely necessary in the later stages to facilitate the melting away of plastic material and young connective-tissue changes. Without mercury it is impossible thoroughly to eradicate the disease and ultimately cure the patient. Some observers contend that the iodides alone are curative. This is a doubtful assertion. Mercury forms the sheet-anchor and is the greatest foe of syphilis. Symptoms of the tertiary stage frequently appear of a dubious character, but the history of the patient and the subsequent objective signs create important links in the chain of our diagnosis. The etiological factor may long have been forgotten or may have been intentionally kept from the practitioner; the same may be said of the secondary manifestations, and no evidences may exist save a general adenopathy. Our diagnostic acumen is very much taxed, but the suspicion of syphilis lurks everywhere about the patient, and here we realize the necessity of the so-called unscientific therapeutic test. Many objections may be raised against this fallacious argument; it is only tentative, but as an example let us take an obscure cerebral disease, with an organic lesion possibly located, but whose character is unknown from its very obscurity; no history of primary infection in youth, no etiological factor to assist us, and yet we are forced to accept syphilis as the most probable factor of its existence, or at least we suspect it. The family history is blank; an examination of the iris and cranial nerves, and an ophthalmoscopic examination of the choroid and the optic nerve, may assist. Providing we find an absence of a definite cause and absolutely no evidence of constitutional syphilis, the query is, what our treatment should be and whether we are justified in tentatively using antispecific remedies.

On the strength of past numerous successes and the rapid amelioration of symptoms and objective signs, though we cannot demonstrate any evidence of syphilis, we are forced to admit the frequency of syphilis as a causative factor, and our justification is well supported by a possible recovery. I am well aware that I am generalizing my remarks and am treading upon somewhat foreign ground, but an admission of ignorance is better than confident assertion of controvertible statements. It is true that heroic antisyphilitic treatment has frequently caused marked amelioration of severe brain symptoms, supposedly due to syphilis, but later demonstrated to be due to other causes widely divergent and not specific in character. The truth of this objection has especially impressed itself upon me in cases of tuberculous meningitis of children, when an apparent lull in symptoms, even holding out hopes of recovery, was caused by the administration of large doses of the iodides and by inunctions, which fact tended to deceive us severely. It is difficult to account for these phenomena, save on the theory that the amelioration of symptoms could be ascribed to an increased absorption of liquid elements by a lymphatic system, whose activity had been markedly increased by the stimulation of the drugs administered. This test is not without its fallacies, and is consequently forcibly held out as irrational by the opponents of specific treatment in chronic cerebral disorders. Yet it must be contended that in these obscure cases palliation is the entire extent of our resources. The query naturally arises, whether we are justified in forcing the patient to submit to a heroic form of specific treatment when the etiological factor is in doubt. As a rule, very little detriment results from such a procedure, and much may be gained in a doubtful case. Justification of aggression by resultant cure in a single case, though it had been merely tentative, will well repay us for a dozen failures. While the plan seems unscientific and irrational, the patient's feelings are very little influenced by adherence to the strict rules of our science as long as we can hold out relief and a possibility of a cure. Especially does this apply to those young in life, when cure signifies much for their future welfare, or, if not a cure, at least a checking of the degenerative process and prevention of subsequent recurrence. Degenerative types of disease, especially with multiple patches of sclerosis as a basis, can be hardly expected to yield to treatment, though it be heroic, as no drug is known which will cause dissipation of firm scirrhous connective tissue. Though the so-called stages of syphilis are an arbitrary division, yet they help us to understand more thoroughly the pathological conditions and the principles upon which a rational treatment of syphilis is based. From our present knowledge we infer that the proliferative cell growth of syphilis produces accumulative lesions, which must be affected by drugs in a way to cause dissipation or dissolution, in all probability by a process of fatty metamorphosis. Syphilitic granulomata, more than any other tissue, in fact characteristically so, completely disappear under proper treatment, leaving no vestige of their presence. This property of causing fatty degeneration is ascribed to the mercurial salts more than to any other drug. When the deeper connective tissues are affected, the iodides are especially useful in stimulating the various lymphatics to increased absorption and in arousing the emunctories to eliminate the products of fatty metamorphosis. Regarding the quantities of mercury and the iodides that effect this change, every case is a law unto itself, except that the drugs should be administered with firmness and heroically. Iodide toleration is usually well marked in syphilis, though various idiosyncrasies play an important rôle in its administration. Iodism, with its well-marked rhinorrhœa, various skin eruptions, and gastro-intestinal irritation, are drawbacks familiar to all. Symptoms of iodism may primarily be well marked and cause an interdiction of iodides; again, they may readily disappear by persistence in the drug. H. Wood even goes so far as to say that if 4 gm. of iodide of potassium is administered three times a day without producing symptoms of iodism, it shows that the patient is afflicted with syphilis. This is a dogmatic assertion, for I have frequently seen proof that idiosyncrasy against the drug is overcome by energetic persistence of administration. On the other hand, a severe syphilitic case may not tolerate even minute doses of iodides without a profound impression and aggravated constitutional disturbance being produced. When danger is imminent and deglutition is impossible, iodides may be administered per rectum. Absorption is notably enhanced by dissolving the iodide in a warm saline enema. Oral administration in the ordinary case, which calls for no particular hurry, requires average doses of from ten to twenty grains three times a day: when danger is imminent, as much as one-half ounce may be administered three times a day, and this without apparent detriment to the patient's health; in fact, as the patient improves he may put on flesh and fat. As a warning in some cases, emaciation may set in and be rapid, owing to the large doses. Careful watch should be exercised to detect this beginning waste and check its further progress. Iodides should always be given well diluted with water, preferably after meals. In but two conditions am I aware of the harmfulness of iodides. The first is in some cases of optic neuritis, in which it facilitates the atrophy and loss of function. In the second, in cases of general or pulmonary tuberculosis, iodides increase the rapid wasting of the tissues. The disappearance or rapid amelioration of grave symptoms under iodide treatment would lead us to infer that the case is specific, or at least would offer strong presumptive evidence of syphilis, though we may have no right to assume this in the absence of a history to that effect.

Our materia medica teems with countless drugs, few of which can be considered true specifics, among which mercury occupies the foremost rank in the treatment of syphilis. Centuries have been unable to weaken the usefulness of this drug; rather has time tended to strengthen our opinion regarding its effectiveness if properly used. Besides having ascribed to it a specific action upon the doubtful germ of infection, it is supposed to act upon syphilitic granulomata, causing them to undergo a process of fatty degeneration which facilitates their absorption.

While the drug has innumerable advantages, it has many disadvantages, especially in the hands of the tyro. One of these is its marked tendency to cause local disturbances in the buccal cavity, affecting the gums and neighboring glands, giving rise to increased salivation and to pain and tenderness. Notably is the condition made worse by vulnerable spots in the mouth, especially diseased gums and teeth, which call for a thorough overhauling before a course of mercurial administration is begun. Certain salts of mercury are more prone than others to produce salivation. Whatever salt be selected by the practitioner, this tendency should always be kept in mind, and the method best adapted to the case should be chosen. There is no doubt that the economy is unable to assimilate the amount introduced, especially if given by mouth, when it has a marked tendency locally to affect the gastrointestinal tract, and if the secretions give a warning of their lessened activity. The emunctories require careful attention, especially if the kidneys seem to be in a state of acute or chronic inflammation, since they eliminate the metal and throw off quite a quantity from the system. A marked pathological condition of these organs may constitute a distinct contraindication to large doses of an irritating mercurial salt.

From time to time various plans of treatment with salts of mercury have been suggested, but the three most prominent ones are the expectant, the continuous, and the interrupted. Each has its advocates; however, rules, especially if absolute, never take the place of brains. From time immemorial the expectant plan has held sway, which consists in administering mercury only when symptoms or objective signs appear. After their disappearance no further treatment is deemed necessary, unless signs of syphilis should again present themselves. The fallacy of this plan is that recurrence in some form usually takes place; in fact, quite frequently an aggravated explosion takes place after a period of quietude. The numerous hospital and dispensary patients generally present themselves only when some manifestation of the disease appears, and receive treatment for the time being, to be lost to view after relief. Recurrences are consequently to be expected; in fact, it is surmised that many severe cerebral cases occurring late in life are due to the short term of medication, which allows the poison to remain latent and to show augmented activity in later life. The continuous plan of medication appears more rational and has many advocates, foremost among whom is the older Keyes, who has formulated many nice rules. He aims at obtaining a saturation point of the system by administering large and increasing doses, as large as the system will tolerate—this only for a limited time. Mild colicky pains and a serious diarrhœa determine this so-called saturation point. These are supposed to show a bare excess of the amount the system can take or tolerate, and half this quantity denotes the tonic dose. The toleration dose and the tonic dose are alternated, the possibility of abdominal symptoms being always kept in mind. After a continued administration of mercury the system seems to adapt itself to its presence, and the doses are apt to lose their therapeutic effect; markedly so is this the case in syphilis. In order to prevent this, some favor the withholding of mercury for some time, in the interim giving tonics and trying to build up the system. Owing to the necessity of withholding mercurial treatment for a short time, the interrupted plan has found many advocates, foremost among whom is Fournier. It must be remembered that those persons who are otherwise in good health present the best subjects for treatment. They respond far more readily; a less favorable nidus exists for the development of syphilitic cells, which are alert for a vulnerable point.

Hygiene offers us an important adjunct to treatment and is responsible for some excellent results obtained at local bathing resorts, where the habits of life of the individual are completely changed. Notable in such respects is abstention from alcohol and tobacco. It has already been indicated that oral administration of mercury calls for watchfulness for symptoms arising from the gums and the buccal glands. Though this is the favorite method of administration, it will be noticed that some salts of mercury produce salivation more readily than others, also that some are more effective than others. The insoluble salts of mercury are still in vogue, though soluble ones appear to have the preference. Green iodide, once a favorite, is weak in its action, while the soluble bichloride is more effective, especially if given in conjunction with the iodide. Oral administration of mercury is especially adapted to the early stages. When it cannot be thus given and when heroic dosage is required, inunctions and hypodermatic injections are preferable. Though the former constitute the most simple and the usual method, they furnish an additional way of introducing mercury into the system. The elegant preparation oleate of mercury has proved an almost signal failure in severe emergencies. Inunctions of unguentum hydrargyri, though not so cosmetic, can be depended upon when a rapid impression is desirable. One or two drachms should be thoroughly rubbed in for about one-half hour daily until physiological effects are produced. Rubbings are at the same time helpful when local lesions exist, though situated in the deeper tissues or in the vicinity. Warm baths in conjunction facilitate the absorption of the minute globules of mercury. The simplicity of this method of introducing mercury into the system has secured for it a host of friends, who prefer it to the hypodermatic method, which has for its bugbear pain. However, when rapidity of action and certainty of dose are desired it can be depended upon, especially if the soluble salt is used. Pain in some cases is probably due to a precipitation of the soluble salt in the blood plasma, which in turn dissolves in the alkaline fluids assisted by sodium chloride. Theoretically and practically, this gives us a hint to use a saline solution for our menstruum, in a syringe capped with a gold-plated needle. The site selected for the injection should be the nates and the deep intermuscular tissues. If injected into the deeper layer of the true skin, a slough results; if into the intercellular tissues, pain usually follows. It is a noteworthy fact that injections seldom affect the gastro-intestinal canal. Solubility of salt should be attained, as insoluble salts must first undergo chemico-physiological changes before they can become absorbed by the lymphatics and pass the lymph nodes. Osmosis becomes more difficult the more radically different the salt is from the composition of the blood serum. Hence it seems to me that oily menstrua holding these salts in suspension are objectionable. Liquid paraffin, almond oil, vaseline oil, etc., are as objectionable as is unaseptic gray oil. Insoluble salts are numerous; calomel seems the most preferable, from the fact that it can be freshly sublimed and is then in an aseptic condition. These injections, of about gr. i. to gr. iss., should be made in a suspended form into the intermuscular tissue of the nates and repeated not oftener than once a week, allowing the salt to become slowly brought into solution. Pain may thus last a number of days, as we have a foreign body in the tissues; and such complications as suppuration and embolism are rather the exception. It appears an unscientific and a risky procedure; one failure makes us apprehensive, and is apt to curtail its further use. On the whole, soluble salts are preferable; but kidney complications should always be kept in view. Intravenous injections of bichloride have been used, and with success, in tropical malarial toxæmia.

While I have but cursorily touched upon some of these interesting points of mercurial administration, much more could be said of a combination of drugs, of legions of drugs, especially of vegetable origin, which have proved signal failures in the treatment of syphilis. The necessity of improving the patient's general health and of placing him in the best hygienic surroundings must be obvious to all. By our knowledge of the physiological functions and of the action of drugs we assist nature to resist the action of venom and successfully to cope with disease. Through the agency of the fluid elements of the body we introduce medicaments known to be capable of coping with an enemy making serious inroads by his destructive ravages—while art assists, nature tends to heal. The deadly comrade of Venus continues to select its victims irrespective of rank or position. In the firmament of our materia medica the constellations present innumerable luminous foci, the majority of which are faint and lustreless, but among a few one remains fixed, full of lustre and lumen, with an indelible inscription upon it—"hydrargyrum."

970 Lexington Avenue.

TREATMENT OF RHEUMATISM AT THE NEW YORK HOSPITAL.[1]

By HUGHES DAYTON, M.D.,

HOUSE PHYSICIAN, NEW YORK HOSPITAL.

The treatment of the various forms of rheumatism at the New York Hospital is practically the same during the terms of service of the four attending physicians, Drs. Peabody, Ball, Loomis, and Lambert.

I. Acute Articular Rheumatism.—In this form rest in bed and a milk diet are naturally employed during the presence of acute symptoms. After their subsidence the diet is increased to fluids, and then to "fluid and soft," as the appetite returns. As in other forms of articular rheumatism, the bowels are carefully kept open, avoiding salines in weak, anæmic subjects, and employing them in plethoric persons. Elimination is also encouraged by the liberal use of alkaline mineral waters. The patients are kept in bed for several days after symptoms disappear, in order to avoid exposure.

Treatment by alkalies has not proved satisfactory in many acute cases. Internally, sodium salicylate is chiefly relied upon, in doses of gr. x.-xv. every three hours except between 9 P.M. and 5 A.M. The frequency is reduced as the pain and temperature abate. If mild toxic symptoms—ringing in the ears and deafness—develop, they are controlled or diminished by the administration of sodium bromide, gr. xxx. with each dose of sodium salicylate, when it is deemed advisable to push the action of the latter as far as possible instead of diminishing the dosage. Poisoning by salicylate of sodium has occurred at the New York Hospital recently in two cases, in both of which only the usual quantity for medicinal purposes had been employed. As an instance of the small amount which may cause this result, the following case is briefly reported:

D. McM——, fifty years of age, was admitted on February 22, 1900, suffering from symptoms of acute articular rheumatism. He was treated by the local application of methyl salicylate to the inflamed joints, and was also given sodium salicylate gr. xv. every three hours, beginning at 2 P.M. After the eighth dose the symptoms had greatly diminished, and the drug was administered only three times a day. When two such doses had been received, the patient became actively delirious, insisted that he felt perfectly well, slept only three hours at night, refused all medication, and demanded his discharge from the hospital. His rectal temperature had fallen from 103.4° to 100° F. on February 24th. He was given sodium bromide ʒ iiss. in divided doses of gr. xxx. and ʒ i., and although the delirium became much less severe he went to his home on February 25th. He returned on March 7th with no mental symptoms, and suffering from general muscular rheumatism which had developed the day before readmission. Under phenacetin and salol the muscular pains rapidly disappeared.

---

[1] Read before the Section on Medicine of the New York Academy of Medicine, March 20, 1900.

If sodium salicylate is not well borne by the stomach, salol in doses of gr. v. every three hours, and salophen gr. xv.–xx., have been satisfactorily employed. The salicylate of sodium has also been administered recently by rectum in a few cases for the same reason. A dosage of gr. xxx. in water ℥ ii. every three hours, and later three times a day, has been employed. No symptoms of rectal irritation have been observed.

In nearly all cases internal medication has been supplemented by local application of methyl salicylate, which has invariably given excellent results in rapidly relieving pain in the affected joints. This is renewed daily until the local symptoms subside. Many cases in which gastric irritability contraindicated treatment by mouth have quickly resulted in recovery when such local use of the drug alone was employed. Methyl salicylate, the synthetical oil of wintergreen, is applied upon a thin compress of gauze wrapped around the joint and covered by gutta-percha tissue, which is held in place by a bandage. The initial sensation of burning is soon followed by relief of local pain, and later of that in other joints. The rapidity with which the drug thus employed enters the general circulation is shown by the fact that its excretion in the urine has been found to begin within thirty minutes after application to the unbroken skin. At the expiration of this time the urine shows a marked reaction to ferric chloride.

If fluid persists in the joints after the other symptoms disappear, a cantharides blister or tincture of iodine is applied; and if infiltration of the surrounding tissues or stiffness of the joints remains, it is relieved by hot-air treatment. The anæmia accompanying the attack is combated with iron, arsenic, strychnine, and cod-liver oil; the cardiac and other complications are carefully watched for, and are treated by the usual methods in such cases and by increase of the salicylate.

Rheumatic hyperpyrexia is rarely met with, but when encountered is treated by large and frequent doses of sodium salicylate and the tub-bath at a temperature of 65° F. for ten minutes every three hours.

II. Subacute Articular Rheumatism.—In subacute articular rheumatism the same internal medication is employed as is used in the acute form, but it is pushed less vigorously. Alkalies and potassium iodide are the most favored lines of treatment, supplemented in all cases by tonics. Locally, methyl salicylate is employed for the relief of pain. Fluid in the joints is treated as in the later stage of acute articular rheumatism; and infiltration of the tissues around the joints by the local hot-air bath. This is applied for one hour daily, at a temperature ranging between 200° and 450° F., to the affected joints; and when persisted in, has given great diminution of the peri-articular enlargement and almost immediate alleviation of the disagreeable stiffness. A fairly liberal diet is allowed.

III. Chronic Articular Rheumatism.—Such cases are rarely accepted at the New York Hospital. They are given internally potassium iodide or alkalies, Vichy in large quantities, a liberal diet, iron, arsenic, strychnine, and cod-liver oil. Locally, the hot-air bath is used persistently. The diet is as nutritious as possible.

IV. Muscular Rheumatism is combated by the administration of sodium salicylate as in acute articular rheumatism, or by salol and phenacetin, āā gr. v. every three hours. Locally, methyl salicylate often gives great relief. Belladonna ointment or plaster is frequently used with the same result. In severe cases no remedy is more efficacious or more rapid in action than the thermocautery applied over the site of pain. One or two applications rarely fail to give complete relief.

V. Sciatica of rheumatic origin is often cured by the same treatment as articular rheumatism, including the local use of methyl salicylate. In the later stages counter-irritation by the cautery, blister, or mustard paste is very efficient. In obstinate cases stretching the affected nerve has been effective and causes only temporary increase of the pain.

VI. Tonsillitis in rheumatic subjects is amenable to salol and catharsis, while phenacetin and the frequent use of a very hot gargle of solution of sodium bicarbonate greatly diminish the distressing pain. Tincture of guaiac is employed in some cases.

VII. Peliosis Rheumatica, so called, though apparently not connected etiologically or pathologically with articular rheumatism, is treated with sodium salicylate in default of any other logical method.

To summarize what has been found at the New York Hospital to be the best routine treatment:

1. In acute articular rheumatism: bed, cathartics, milk diet during the acute stage, sodium salicylate by mouth or rectum, combined with sodium bromide if cerebral symptoms follow the administration of that drug, and methyl salicylate locally. In the later stages the methods employed in the subacute form are used.
2. In subacute articular rheumatism: bed if symptoms are severe, fairly liberal diet, alkalies or potassium iodide internally, methyl salicylate locally for the relief of pain, and the hot-air bath for stiffness or peri-articular enlargement.
3. In chronic articular rheumatism: nutritious diet, alkaline waters in large quantities, potassium iodide or alkalies, and the hot-air bath.
4. In muscular rheumatism: salol and phenacetin internally; locally, methyl salicylate, the cautery, or belladonna.

In conclusion I would call attention chiefly to the use of sodium bromide in combination with sodium salicylate for combating cerebral symptoms and permitting larger dosage; to the hot-air treatment in subacute and chronic rheumatic conditions; and to the value of local treatment by methyl salicylate, which possesses the following advantages: (1) Rapid relief of pain; (2) avoidance of gastric irritation.

NEW YORK HOSPITAL.

The Clinical Thermometer as a Germ Carrier.—W. L. Conklin examined six thermometers for bacteria. Four had been washed but not sterilized. Micro-organisms of one or another variety were found on each of the four. Two had been washed and then placed in a case containing bichloride solution. No micro-organisms were found on either. The author urges the necessity of a more thorough cleansing of thermometers, and describes the case which he fills with a 1:500 or 1:250 bichloride solution, in which he keeps his thermometer.—*Buffalo Medical Journal*, February, 1900.

SUMMARY OF CASES OF CARCINOMA AND SARCOMA TREATED BY THE WRITER'S METHOD OF CATAPHORIC STERILIZATION, TO JANUARY 15, 1900.

By G. BETTON MASSEY, M.D.,
PHILADELPHIA.

In the Medical Record for July 31, 1897, the writer reported a number of cases of malignant growths treated by a new method, involving the massive cataphoric diffusion of the nascent electrolytic salts of mercury. The interest aroused within the profession by the claims made in that article, and in other subsequent publications, suggests the present résumé of all cases treated by myself, which includes the ultimate results in quite a number of cases of from two to five years' standing.

The process may be described briefly as a cataphoric diffusion of nascent mercuric salts produced by the electrolysis of metallic mercury inserted by a gold-anode into the growth, the patient being usually under general anæsthesia, and the chemical and cataphoric force being a direct current of 200 to 1,200 milliamperes continuously employed for a time varying from fifteen minutes to two hours and a half. The immediate effects are the production of an area of necrosis involving the most evident portions of the growth, beyond which extends a zone of sterilization, in which the malignant germs are killed without destruction of the normal tissue elements. The zone of sterilization radiates in all directions, but more especially through cellular planes of cancerous proliferations.

Since the inception of this process of destruction and sterilization of cancerous growths in 1893 I have applied the method to thirty-seven cases, including a number that afterward showed that metastases had been present before the treatment. These cases may be classified as follows:

Operable cases: Cured, 4; probably cured, 1; failed to cure, 2; total operable cases, 7.

Inoperable cases: Cured, 6; probably cured, 2; probably failed to cure, 2; failed to cure, 20; total inoperable cases, 30.

Total cases, 37; cured, 10; uncertain, 7; failed to cure, 22.

Of the thirty-seven patients two died under treatment—one with an inoperable epithelioma of the tonsil and the other with an inoperable sarcoma of the orbit, the latter in a child aged five years. Of the ten patients cured but two showed recurrences, necessitating additional applications, and both patients are now well, after considerable periods since the second applications.

Summary of the cured cases:

Operable cases cured: 1. Epithelioma of the cervix uteri, confined in seat to the vaginal portion, in a lady aged forty-nine years. Repeated mild applications were made in June, 1896. The patient continues in perfect health, three and a half years after application.

2. Acinous carcinoma of the breast in a lady aged fifty-one years, without glandular involvement. The growth was about two inches by one inch in extent, situated in the lower outer quadrant of the right breast. One strong application (475 milliamperes) was made November 16, 1898. The patient remains in perfect health at present, a year and two months after the application.

3. Epitheliomatous wart on the face in a feeble man aged seventy-nine years, was removed by a series of mild applications in June, 1898.

4. Carcinoma of the breast, with infected axillary gland, in a woman aged forty-four years, was treated by one strong application, April 13, 1899 (300 to 500 milliamperes for one hour and twenty minutes). The primary growth was in the outer quadrant of the left breast, involving about one-quarter of the gland, the skin being adherent and changed in texture over the growth. There was one enlarged gland in the left axilla which was subjected to the treatment at the same time. The patient is well and with perfectly healthy cicatrices at the present time, nine months afterward, and possesses also the greater part of the breast intact.

Inoperable cases cured: 5. Sarcoma of the soft and hard palate in a man, aged thirty-eight years. The patient was nearly in extremis from suffocation and inability to swallow, the growth being the size of a goose egg and nearly occluding the fauces. The treatment was by repeated applications of the mild method in 1894. He continues well, at the end of six years.

6. Adeno-carcinoma of the upper rectum in a lady aged fifty years. Repeated applications of 100 to 125 milliamperes were made in 1895. The patient was well when last heard from, some years later.

7. Sarcoma of the upper maxilla in a man aged thirty-nine years. The growth filled the right antrum, causing a bulging of the cheek and flattening downward of the hard palate on that side, and projected into the mouth, having displaced four teeth. On October 11, 1897, an application was made under ether, 300 milliamperes being employed to electrolyze and diffuse the mercury for fourteen minutes, the result being incomplete by reason of the instruments being too short. Subsequent repeated mild applications were made without ether. The man has perfect health at present, over two years later, the distortion of the bony plates having disappeared, and a healthy sinus now leading into the antrum.

8. Recurrent carcinoma of the breast and axilla in a lady aged sixty-three years. The breast and a diseased gland in the right axilla had been removed by the knife ten months before the case was seen by the writer, December 11, 1897. The disease had recurred in the scars at both sites and in the skin of the chest between the breast scar and clavicle. On this date a cataphoric application was made with 500 milliamperes for fifteen minutes. The diseased scar in the axilla was not disturbed until a year and a half later, August 16, 1899, when an application with 200 milliamperes was made, lasting twenty-five minutes. The patient is in perfect health at present, with both scars soft and normal.

9. Inoperable carcinoma of the mouth in a woman aged fifty-six years. The growth was situated beneath the left side of the tongue, evidently developed within the left sublingual gland, with extension along the floor of the mouth as far back as the base of the tongue. On December 28, 1897, an application was made with 350 to 400 milliamperes for half an hour. The result appeared perfect for a time, but in June, 1899, there was evidence of a similar growth in the opposite sublingual gland, which received an application on June 24th, 4,000 milliamperes being employed to diffuse the mercury for one hour. This resulted in destroying the disease on that side, and a piece of devitalized lower jaw subsequently came away. On November 3, 1899, it was noted that a recurrence had appeared at the site of the first application, and a third cataphoric diffusion of mercury was made at this date. At the present time this has healed except for a portion of bone sequestrum which is coming away, and the patient appears to be free from the disease and in good health, though the tongue is somewhat bound down and the inner sides of the lips are contracted by healthy adhesions.

10. Inoperable rodent cancer of the face in a physician aged sixty-six years. The case was of twenty years' duration, had been operated on by the knife two years before, and had recurred in worse form when first seen, January 16, 1899. The disease was situated

on the right side of the face, extending from above the eyebrow to the middle of the cheek, the bone of the skull and upper maxilla being eroded, and the disease was just reaching into the orbit. The patient was placed on mild zinc-mercury cataphoric applications daily, and at the end of three months the whole of the area except a small spot had filled in with healthy skin and flesh—not scar tissue—the skin spreading inward from the edges. Another series of applications was made in the summer of 1899 to the remaining spot, and at the present time the disease is thoroughly eradicated, and the face has completely healed.

Cases probably cured: 1. Inoperable recurrent adenocarcinoma of the neck in a lady aged fifty-seven years, in whom the submaxillary gland of the same side had been removed by the knife one year before. An application was made June 23, 1899, the mercury being diffused by 300 to 400 milliamperes for fifty minutes. Condition, November 1, 1899, well healed with healthy scar. I have been unable to hear from the patient since.

2. Inoperable primary carcinoma of the uterus and vagina in a lady aged sixty-one years, in whose case surgical interference had been declined at the Cancer and Mt. Sinai hospitals in New York City. The growth was a scirrhous epithelioma arising in the cervix uteri and infiltrating the left broad ligament and vaginal walls, a large indurated mass extending down the recto-vaginal septum nearly to the anus. Application was made on December 10, 1899, the mercury being electrolyzed and diffused by a current of 400 to 600 milliamperes for fifty minutes. On recovering from the ether the patient noted a cessation of pains in the back and thigh, though the soreness from the operation was very great. At the date of discharge, January 10, 1900, the parts were well healed, leaving a recto-vaginal fistula, but the softness of the newly formed tissue within the vagina, coupled with continued absence of the cancer pains, made a cure seem possible.

3. Inoperable recurrent carcinoma of both breasts and both axillary regions in a lady aged forty-one years. The right breast and diseased glands in the right axilla had been removed by the knife in June, 1899. Three months later a second operation had been performed for recurrence in both scars and also for diseased glands in the left axilla. Three months later, when seen first by the writer, December 8, 1899, there were a recurrent growth about eight inches long in the situation of the breast scar, and recurrent growths in both axillæ. Across the upper portion of the left breast three nodules showed, revealing the lymphatic-vessel route by which the disease had gained access to the left axilla. An application was made December 16, 1899, of 600 to 700 milliamperes for two hours and a half, permitting the whole of the diseased areas to be gone over with the gold-mercury electrodes. The patient reacted well from the prolonged etherization, and has done well since, there being apparent evidence of all the diseased cells being killed in both axillæ and in the principal recurrent area, except possibly a small spot in the latter, which may demand a second application within a few weeks.

Analysis of the cases of failure to cure: Of the thirty-seven cases, twenty-four have been recorded as failures or probable failures. Deducting the two cases in which death occurred during the application, we have twenty-two cases of failure to arrest the disease, without any bad consequences following the treatment itself. The cause of failure to arrest the disease in nine of these cases was the development of latent metastases after the method had secured a local eradication of the primary growths, the metastases developing in each case without evidence of recurrence at the primary seat, showing that they were due to the lodgment of emboli from the primary growth previous to its destruction by cataphoresis. In the remaining thirteen cases there was failure to arrest the disease locally in the stage in which it was found, many of them being already recurrences after knife operations; and these failures to arrest were due to insufficient diffusion of mercury for various reasons: either failure to use anæsthesia and a strong current, or failures of batteries to give enough current in the early applications, or the fact that the growth was so close to the brain as to make an effective current impossible.

Prostatic Affections in Young Men.—James Ross says that the most important causation of inflamed prostate in young men is no doubt gonorrhœa. In the treatment of membrano-prostatic catarrh the writer has had good results from the topical application of nitrate of silver, beginning with a few drops of a solution five grains to the ounce and increasing the strength.—*Maritime Medical News*, January, 1900.

Operation on the Pharyngeal Tonsil; Hæmophilia; Death.—R. Sachs operated on a boy, aged ten years, under chloroform, using a modified Gottstein knife. The tonsil was removed in one piece as large as a walnut. Bleeding at the time was no more than usual, and the child was sent home, but he began to bleed again in a few hours. Hemorrhage recurred at intervals; it was temporarily checked, but recurred again, and the child died on the fourth day. Later inquiry revealed the fact that his maternal grandfather had died at the age of forty-two years of hæmophilia (renal hemorrhage). The child had also manifested in previous years evidences of the same disease.—*Journal of Laryngology*, February, 1900.

The Alterations in the Venous Coats in Varices.—Raffaele Ianni finds that in varicose veins the retrogressive changes in the walls are due not only to their passive distention but also to sometimes extensive new formations of connective tissue, chiefly in the intima—an endophlebitis resulting in nodes or plaques. The elastic fibres of the internal limiting membrane become thinner, and there is new formation of these fibres also. In the innermost layers of the media there is apt to be a circumscribed connective-tissue new formation in the vicinity of the nodes and plaques. This endophlebitis is primary, and does not possess the compensatory powers ascribed to it by Epstein.—*Gazzetta Internazionale di Medicina Pratica*, February 15, 1900.

A Type of Enteric Fever—Not Typhoid.—Otto Lerch claims that there is a type of enteric fever, not typhoid, which is probably caused by one of the varieties of the bacterium coli commune. He reports a case which he believes to come under this head, in which, after an illness somewhat resembling an atypical typhoid, the patient suddenly died of heart failure. In this case, the fever chart did not resemble typhoid, not even atypical typhoid: the onset was sudden, though prodromes seem to have preceded it; the eruption was peculiar, and tremor was not present, especially tremor of the tongue, a symptom to be looked for in typhoid; the examination of the urine showed the diazo reaction absent, and the blood count showed an enormous increase of white blood corpuscles, never met with in an uncomplicated case of typhoid. At the autopsy the gall bladder was found intact, and the mesenteric lymph nodes were not perceptibly enlarged. The author thinks that the foregoing summary justifies the conclusion that the case represents a type of enteric fever not caused by the bacillus typhosus.—*New Orleans Medical and Surgical Journal*, February, 1900.

THE URIC-ACID DIATHESIS.

A PAPER on "Uric Acid and the Circulation, Some New Methods of Estimating its Effects," read at the meeting of the British Medical Association in August last, by Dr. Alexander Haig, and recently published in pamphlet form, is instructive even if regarded as simply elucidating the well-known original views of the author on the subject. Although Dr. Haig is decidedly too prone to lay at the door of uric acid most of the diseases to which the human race is liable, and thus prejudices his case by the very excess of zeal with which he fights for his cherished theory, nevertheless it must be admitted in common fairness that his investigations have not been unfruitful of results, and that he has done good service in insisting upon the importance of the part played by uric acid in the causation of certain diseases. There would at least seem to be a solid basis for some of his reasoning. Since the discovery by Garrod, in the middle of the last century, that the blood and interstitial fluids of gouty persons are surcharged with urates, pathologists have been veering with ever-increasing steadiness to the conviction that uric acid is the ruling factor in the causation of gout. It is also conceded that uric acid may probably be rightly regarded as a dominant cause of other diseases, notably migraine. The medical profession considers that this supposition requires further and stronger proofs before being accepted as an established fact. As yet many links are lacking to render the chain of argument complete.

Haig states in regard to migraine that "the greater the relative excess of uric acid and the greater its absolute excretion per hour, the more severe the headache." Dr. Lichty, of Pittsburg, questions the accuracy of the statement, in an article published last year in the *Journal of the American Medical Association*, Dr. Lichty having demonstrated by careful experiments on persons suffering from migraine that the quantity of uric acid excreted was not increased during the most severe part of the attack. But the particular point upon which Dr. Haig differs most widely from other authorities is as to the means whereby uric acid obtains ingress into the system, asserting that it is introduced into the body as such in certain articles of food, and he further claims to have detected uric acid in the blood by microscopical examination, a contention stoutly denied by other workers in the same field of research. The opponents of the first theory declare that these conclusions have been reached by processes altogether unsatisfactory to an organic chemist; while in regard to the second theory Dr. Luff says that uric acid has never been demonstrated in the blood by the one infallible test—the murexide test—and his opinion is that it is urea in the blood which has been converted into uric acid in the kidneys.

The writer of a review in the *British Medical Journal* on the last edition of Dr. Haig's work, "Uric Acid as a Factor in Disease," records his views as follows: "Numerous investigations have plainly proved that uric acid is entirely absent from the blood of a healthy man, as also from the blood of other mammals and birds. Dr. Haig's explanation of the causation of the numerous diseases attributed by him to uric acid is based upon the assumption that uric acid is deposited in the colloid form throughout the organs and tissues of the body." Dr. Haig in his paper thus describes his methods of estimating the effect of uric acid on the circulation. He first refers to the tediousness of the ordinary tests made use of for this purpose, and goes on to say: "I have therefore been in search of a test which might be completed more quickly in patient after patient without loss of time and almost without any instruments. This test, it has long appeared to me, I might obtain if I could measure accurately the capillary circulation or its effects in the retina, for instance; and an observation made by Raynaud led me to the more generally useful measurement of the rate of capillary circulation in the skin. Raynaud says that when the vessels in the skin of a finger affected by local asphyxia are emptied by pressure, as much as thirty seconds may elapse before it regains its color, while in the skin of a normal extremity the color returns in one or two seconds. It struck me that if there is all this difference between the normal return and the pathological return, and if Raynaud's disease is, as I have suggested, due to collæmia, I might find differences in time of return of the blood corresponding to the physiological drug action, and other pathological fluctuations of uric acid. . . . I accordingly began to measure experimentally the times of what I call the capillary reflux—that is, the time in which the color returns in, say, a given area in the back of the hand when removed by pressure. And after a time I adopted an instrument which gives a constant definite area of pressure, a definite and measurable force, the pressure being applied for a definite and constant time, measured by a metronome beating half seconds, the length of time the blood and color take to return being measured by the same instrument. With regard to the eye, I eventually adopted the measurement by the same metronome of the duration of a certain phase of the 'after image' produced by a constant light at a constant distance, and with a constant time of exposure." Dr. Haig says that he found that these tests recorded in the most striking manner all the marked fluctuations in the excretion of uric acid, whether due to the physiology, drug action, or pathology. The capillary reflux acts synchronously with high blood pressure and with the disappearance of the after or fatigue image in the retina indicating the capillary circulation there. He therefore claims that testing this capillary reflux is an index of the amount of uric acid in the blood and urine, and that capillary circulation is controlled by uric acid.

If, as asserted by Dr. Haig, high blood pressure and defective capillary circulation are constant concomitants of the headache and mental depression due to uric acid, and if uric acid can be introduced into the body by means of food, and if it is present in the blood of a healthy man, then the tests devised by Dr. Haig to estimate its effects on the circulation would certainly be in a high degree useful. But the fact must be borne in mind that there is no absolute proof that migraine is caused by an excess of uric acid, although the observations of Dr. Haig in his own case, and his successful treatment of those who have been guided by his advice, would seem, so far as that disease is concerned, to point that way. In regard to the other two theories, they are, as we have said before, judging by the mass of evidence brought against them, entirely hypothetical.

WOMEN AS ARMY NURSES.

In the treatment of the sick and wounded in war-time careful and tender nursing is almost as important as is skilful surgical and medical attention. The surgeon, especially after a great battle, cannot give much time to each patient, and must depend upon the nursing corps for the minute carrying out of his directions. It is therefore a matter of the first moment that this necessary branch of the medical department of an army in the field should be thoroughly well trained and organized. Military nursing differs in so many respects from ordinary hospital nursing, that a special course of instruction is requisite in order to gain a competent knowledge of the duties which may devolve upon an army nurse when a campaign is in progress. The question was raised in our war with Spain and is again being brought into prominence in the South African war, as to whether men or women are better fitted to fill the position of army nurses. So far as the nursing itself is concerned, there can be little doubt that women are superior to men. Sir William MacCormac considers women better fitted both physically and morally for the charge of the sick. He has put it on record that in his opinion no male nursing can be compared with a woman's, although no one insists more than he upon the necessity of training.

In the Crimean war, after Florence Nightingale arrived upon the scene, and in the Franco-Prussian war almost all the nursing of the British and German troops respectively was performed by women. Nevertheless many experienced authorities hold, among whom are Surgeon-General Sternberg and those at the head of the British Army Medical Corps, that the front is no place for women. A writer in *Blackwood's Magazine* for March writes as follows:

"There is no doubt that in the line nearest the enemy, where work must be to some extent rough and ready, when grave danger is hovering near, and a hospital must, as it were, 'come into action' with the utmost rapidity, and not always under the most favorable circumstances, the men of the Royal Army Medical Corps are the best possible nurses. It has been suggested that some lady nurses should be attached to the field hospitals; but the consensus of opinion among those who are responsible that the work is well done, and among the poor Tommies who form the cases, is that the ladies would be quite out of place so near the battlefield and that it is much better to rely entirely on the men who have always proved themselves to be so good and efficient. It is obvious too that if a lady nurse falls sick it would be impossible in a field hospital to provide that she should have the care and privacy due to her sex. The British Army Medical Corps consists not only of medical officers but of a large body of trained male orderlies. These latter are the real nurses who do the actual nursing work, and they are under the orders of a highly efficient and limited body of trained lady nurses who act practically as ward sisters, and who while directing the orderlies do not take any active part in nursing the wounded. . . . The first and second lines of assistance are entirely composed of men, and it has comparatively seldom happened that a female army nurse has ever been anywhere near a field of battle except owing to some circumstances over which her medical superiors had no control."

But although women may not be physically capable of coping with the onerous duties which fall to the lot of nurses with an army in action, still this is no reason why their services should be wholly dispensed with in time of war. The hospitals in the rear should always provide an ample field for their usefulness, and it seems to us that the nursing staff of these hospitals might be with advantage largely if not entirely composed of women—that is, of women who have been well trained in the routine of army hospital methods. In order to have an efficient women's nursing service in time of war it will be needful for the United States army authorities to see that the candidates are carefully selected and afforded the opportunity of gaining experience in army methods.

THE MIDWIVES BILL IN GREAT BRITAIN.

The licensing of midwives in Great Britain, despite the fact that, as shown by the result of the ballot among the medical practitioners of that country initiated by *The Lancet*, the profession as a whole is strongly opposed to the measure, will, it appears, shortly become law. The necessity for such legislation is no more apparent to the medical men of England that is the proposed legislation for the licensing of midwives in this city to the physicians of New York. *The Lancet* says in reference to the obnoxious bill: "What now remains to be done is for the medical profession to bring such influence as they possess to obtain modifications in the measure: (1) whereby the general practice of midwifery in our country may not fall into the hands of a semi-educated class; (2) whereby the scope of the licensed midwifery shall be defined; and (3) whereby encroachments upon medical practice and infringements of the medical acts may be obviated." The same journal thus defines what should be the scope of a midwife: "The due limits of the midwife's work in an ideal condition of things would keep her to nursing and nothing but nursing, including the first care of the infant if healthy. In such an ideal condition of things the whole province of obstetric medicine belongs to the fully qualified medical man, for it is obvious that at one particular place or another a case passes from physiology to pathology."

The licensing of midwives is a retrograde step and one likely to prejudice severely the interests of the medical profession. It will establish a precedent for the licensing of so-called experts of every description, and will open the door to quackery generally. Laws medical and otherwise are made only for the protection of the public. No class of the community needs protection more than parturient women, and it would therefore appear reasonable that the law should insist that women in this condition should have the benefit of skilful and intelligent treatment. This object will not be effected by the licensing of midwives.

ISCHÆMIC PARALYSIS.

Paralysis of a member with rigidity or contracture is sometimes observed following the application of a bandage, and the condition has usually been attributed to nerve pressure too firmly made or too long continued. In the latter event some importance has also been attached to want of use. On the other hand, interference with the blood supply, with the resulting nutritive disturbance in the muscles, has been thought to be the active pathological factor. Necrobiotic changes have been found in muscles that have been rendered bloodless by circular constriction and also after exposure to severe cold. Once developed, the disorder has proved a most obstinate one. In a case in which such a condition developed in a child four and one-half years old, following a fracture of the humerus and the application of splints and a bandage, Page (*Lancet*, January 13, 1900, p. 83) secured a satisfactory result by lengthening the tendons of the affected muscles and long-continued massage and electric treatment. The disabled extremity was the seat of great pain, and the wrist and fingers were in a position of marked flexion. The ulnar distribution in the hand was anæsthetic, and degenerative reactions were present in the affected muscles. Improvement was slow, but eventually quite considerable. The opinion is expressed that the condition, in this case at least, is not primarily or even in the main due to a nerve lesion, but is dependent upon the combined effects of pressure, immobility, and diminished blood supply upon the muscular elements, the connective-tissue elements, and the nerve elements present in the muscle.

A New Hospital for the Insane has just been completed at Bridgeton, N. J., the handsome and commodious structure being formally turned over to the county by the building-committee on March 29th.

News of the Week.

Dr. Schenk, recently dismissed from the chair of embryology at the University of Vienna for having exploited his theories of sex determination in the newspapers, announces that he will probably come to America.

Statistics of Laryngectomy: A Correction.—Dr. D. Bryson Delavan writes: "In the Medical Record of March 24, 1900, page 523, I am reported as having said in the discussion of a case of laryngectomy presented to the surgical section of the New York Academy of Medicine by Dr. A. T. Bristow: 'Partial laryngectomy does not show more valuable statistics than the complete operation, and the results of complete extirpation are so much better that there can be no choice between the operations,' etc. The statement bears upon a subject of such great importance that the misquotation of it should not go uncorrected. What I actually said expressed not only my own views, but the generally acknowledged opinion with regard to this matter, namely, that exactly the contrary of the above-quoted statement is true."

Work among the Lepers in the Far East.—One of the most interesting themes that will be considered at the Ecumenical Missionary Conference in New York, April 21st to May 1st, relates to the work done for lepers in various parts of the world. It is to be specially reported on by Wellesley C. Bailey, secretary and superintendent of the Mission to Lepers in India and the East, and by Miss Mary Reed, a missionary to the lepers. The mission to lepers in India begun in 1874 found a necessitous sphere of work among this large and afflicted class. There are nearly half a million lepers in India alone, and large numbers are to be found in other eastern lands. There are now fifty-two leper asylums in India, Burmah, Ceylon, China, Japan, and Madagascar. Much of this advance is said to be due to Mr. Bailey, who joined the American Presbyterian Mission in the Punjab in 1869, and spent twelve years in India, working among the lepers and part of the time having charge of two leper asylums. In 1874 he visited Ireland. Securing the promise of $150 annually for the relief of lepers, he established the mission for them. In 1893 the title was enlarged and the society became "the Mission to Lepers in India and the East." In 1897 the mission helped nine British and several other missionary societies, and had twenty hospitals of its own, a number of homes for the untainted children of lepers, and expended $37,960 in its work. The number of inmates in the mission homes is about one thousand, and there are about seventeen hundred in aided institutions.

A Physician Punished for Incapacitating Recruits.—Dr. Adolph Ziel, of Elberfeld, Germany, has just been sentenced to a year's imprisonment for having assisted conscripts in avoiding military service. His plan was to give some cardiac poison just before the conscript was to be examined, so that the heart would be found irregular in its action. He had cheated the government out of over three hundred soldiers before he was apprehended. Several military surgeons were also sentenced to short terms of imprisonment for complicity in his scheme.

The Medical Association of Missouri.—The forty-third annual meeting of this society will be held at Mexico, Mo., on May 15th–17th. The subject for formal discussion will be "Gall Stones."

The Pennsylvania Society for the Prevention of Tuberculosis.—The annual meeting of this society will be held on Wednesday, April 11th, at 4:15 P.M., at the Academy of Natural Sciences, Logan Square, Philadelphia.

The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered at the Academy of Medicine on Friday evening, April 13th, at 8:30 o'clock, by Dr. Simon Flexner, of the University of Pennsylvania. The subject of the lecture will be "The Pathology and Etiology of Dysentery."

Normal Appendectomy.—The St. Louis *Medical Review* of March 17th contains replies from eighty-nine surgeons in different parts of the country regarding the advisability or justifiability of removing the normal appendix as a prophylactic measure. Only one expressed unqualified approval of the operation, and three seemed to be in favor of it with reservations.

A Memorial to Dr. Love.—The Love Memorial Association of Montclair, N. J., has presented to the Free Library Association a bronze bust of the late Dr. John J. H. Love, made by J. Scott Hartley. Charles H. Johnson, president of the association, reviewed the life of the physician and his services to Montclair, and then formally presented the bust to the library. Edwin B. Goodell made the speech of acceptance.

A Mental Healer Not Wanted in Belgium.—It is reported in London that a "professor of mental healing," an American citizen, has complained to the government of this country that he was expelled from Brussels by the Belgian minister of justice. It is to be hoped the Belgian authorities will be induced to retract their edict of expulsion, otherwise the "healer" might return to this country.

The Louisiana State Medical Society.—At the meeting of this society in New Orleans, on April 19th–21st, there will be a special subject for discussion before each of the several sections. In the section on medicine the subject will be "Tuberculosis"; in that on surgery, "Local and Regional Anæsthesia in its Applications to Minor and Major Surgery"; in that on obstetrics and gynæcology, (1) "Surgical Aspects of Salpingitis," (2) "Electricity in Gynæcology"; in that on pediatrics, "Measles and Smallpox in Children."

The Plague.—It is stated that two hundred and seventeen deaths from plague occurred in Calcutta on March 27th, the number of new cases reported the same day being one hundred and fifty-seven. In Sidney, N. S. W., eleven new cases were reported on April 1st, and two deaths occurred. In Honolulu, on March 24th, it was stated that no new cases of pest had developed in over a week, and the board of health was considering the advisability of announcing officially that the epidemic had run its course.

The New Naval Hospital at the Mare Island yard in California has been completed and is now ready to be turned over to the government. It is pronounced one of the best-equipped hospitals in the country.

Typhoid Fever on the Prison Ships.—A despatch to *The Sun* from Cape Town says that rumors are current there that there are not enough doctors and nurses on the prison transports, upon which an epidemic of typhoid fever is raging. Many civilians have offered their services.

The New York City Hospital for Consumptives.—Dr. Henry's bill to provide for the establishment by the city of New York of a hospital for the regular treatment of pulmonary tuberculosis, and appropriating $350,000 therefor, passed the Assembly last week. The local board of health is to have jurisdiction over the new hospital.

St. Bartholomew's Clinic.—A member of St. Bartholomew's Church has given $155,000 for a new building and equipment for the eye, ear, nose, and throat clinic maintained by that parish. Ground has been purchased, and the new building will soon be erected on East Forty-second Street adjoining the present mission building.

The Hospital Ship "Maine."—A protest was recently lodged by the committee in London against the return of the *Maine* from South African waters. General Buller in reply said he thought that the ship in going to England would confer the greatest benefit upon the sick and wounded, as, with her excellent medical staff, she would aid in that way the evacuation of bad cases from the congested hospitals. He added that if she went to England, her return would be desired at the earliest possible moment.

Hospital-Ship Investigation.—The Secretary of War has appointed Brig.-Gen. Alfred E. Bates, paymaster-general, Major Henry S. Kilbourne, surgeon, and Major John M. Carson, Jr., quartermaster, on a board to make inquiry into all the facts relating to the equipment of the hospital ships *Missouri* and *Relief*. The cause of the appointment of the board was a request for a large sum of money to place the ships in a seaworthy condition. As both were only recently fitted up at great cost, the secretary wishes to know why they have so soon become unseaworthy.

Progress in Great Britain.—At an inquest recently held in Belfast the coroner remarked that the post-mortem examination had been made very satisfactorily by Dr. Harriett Niel, and that this was the first instance on record in the country of such a public duty having been discharged by a woman. Another sign of diminishing prejudice is furnished by the announcement that medical women will be admitted to the Liverpool School of Tropical Medicine on equal terms with men. In view of the fact that many medical missionaries are women, it would seem only reasonable to give them every opportunity to fit themselves for their future work as far as possible before leaving England.

The Eastern Medical Society.—The annual dinner of this society took place at the St. Denis Hotel on the evening of March 23d. There were one hundred and seventy-five guests, including ladies.

The American Surgical Association.—The annual meeting of this society will be held in Washington, in connection with the Congress of American Physicians and Surgeons, May 1–3, 1900. The address of the president, Dr. Robert F. Weir, of New York, will be on "Perforating Ulcer of the Duodenum." The subject for set discussion will be "Surgery of the Stomach." Titles of voluntary papers will be received by the secretary, Dr. Herbert L. Burrell, up to April 10th.

The Tropical Army Ration.—Dr. Munson, in the essay which was awarded the prize of the Military Service Institute offered by Dr. L. L. Seaman, holds that the present army ration contains too much nitrogenous food and hydrocarbons and not enough carbohydrates, and the ration in general is too large. "It is evident," he says, "that such changes as are advisable in the adaptation of the United States army ration to tropical conditions are chiefly in the line of a reduction in the quantity of the foods at present provided by a too generous government. It is true that the sugars and starches should be slightly augmented, but their increase is small when compared with the considerable reduction of nitrogenous and fatty matter which is proposed. Many of the components of the present ration, as is seen by the table, require no change in the consideration of the tropical dietary, being not only admirably selected, but also properly proportioned." The quantities of the various components of the rations are given in the following table:

Articles.	Quantity per Ration (ounces.)
Fresh beef (quarters)	10.00
Fresh mutton	10.00
Pork	6.00
Bacon	6.00
Salt beef	10.00
Dried fish (cod)	10.00
Fresh fish, average (whole)	14.00
Flour	18.00
Soft bread	20.00
Hard bread	18.00
Cornmeal	20.00
Beans	2.40
Peas	2.40
Rice	4.00
Hominy	4.00
Potatoes	16.00
Potatoes, 80 per cent. and onions 20 per cent.	16.00
Potatoes 70 per cent. and canned tomatoes 30 per cent	16.00
Dried fruit (average)	3.00
Sugar	3.50
Molasses	1 gill
Cane syrup	1 gill

Philadelphia Neurological Society.—At a stated meeting, held March 26th, Dr. F. A. Packard presented a case of possible acromegaly. The patient was a young man who presented enlarged nasal bones, overhanging brows, a projecting lower jaw, immense maxillary arches, somewhat enlarged hands, and a striking facies, but there was no headache or bitemporal hemianopsia, or other symptom of pituitary tumor. There had been no recent marked increase in growth, and the patient had presented a similar appearance for many years. There was present also a condition resembling elephantiasis of the legs, but this was attributed to repeated inflammation of the cellular tissues. Dr. F. X. Dercum exhibited a man who presented tonic spasm of various muscles on voluntary effort after a period of rest. The condition was not believed to be Thomsen's disease, and its nature was not clear, further than it appeared to be a form of multiple myospasm. Dr. W. G. Spiller reported a case of poliomyelitis resembling Landry's paralysis in an adult. He exhibited also the brain from a case of congenital blindness. The patient had been an idiotic boy, without eyeballs and orbits, who had never spoken, and there was found an absence of the optic nerve and of the chiasm. The pulvinar was preserved, as well as the anterior quadrigeminal body, but the external geniculate body was absent. The entire occipital lobe was much diminished in size, and particularly the cuneus. The upper portion of the anterior central convolution on one side was much narrowed, and this seemed to account for a contracture that was present in the upper extremity on the opposite side. The external arciform fibres of the medulla were unusually distinct. Dr. Stewart Paton presented a communication entitled "The Study of Mental Diseases." He dwelt upon the utility of laboratory investigation, but pointed out that careful clinical study is not less essential. He briefly outlined the plans contemplated for the Sheppard and Enoch Pratt Hospital for the Insane near Baltimore. Dr. J. Hendrie•Lloyd read a paper entitled "Rhythmic Motor Disorder in Hysteria," in which he referred to the case of a girl who presented rhythmic movements of both extremities on one side which were dissipated by suggestive therapeutics, and in whom convulsive seizures apparently of epileptic character also occurred.

Pure-Food Legislation.—The MEDICAL RECORD is in receipt of a communication from Hon. H. C. Adams, dairy and food commissioner, Madison, Wis., referring to the criticism of the Babcock bill in our issue of March 17th. He says: "Section 8 of the Babcock bill, which authorizes the food commissioner to call upon the Association of Official Agricultural Chemists to determine standards, was put into that bill rather against my judgment. As I stated before the Pure-Food Congress and also before the committee on interstate commerce, I do not believe that any outside official body can have the power to determine standards which shall be accepted in court, because it would appear to be a delegation of legislative authority which no man or body of men outside of a legislature could exercise. I agree with you that that section ought to be eliminated, and shall so inform Mr. Babcock. I have observed the comments in the MEDICAL RECORD with reference to section 11. I think you misapprehend the purposes of this section. It is not to protect manufacturers, manipulators, compounders, or dealers in compound mixtures or imitation, but it is to relieve transportation companies from prosecutions under the law. You can readily see that it is almost impossible for a transportation company to know what is the character of the products which it transports. A transportation company certainly could not be expected to open packages and subject them to chemical examination, and the purpose of that section is to throw the whole burden of the law upon the men who make or deal in goods the sale or manufacture of which is prohibited by law. I think you will decide, upon reflection, that that section is a reasonable one." Mr. Adams, we understand, was one of the authors of the Babcock bill.

Dr. Edward Chapin, of Brooklyn, has been appointed by the State board of regents a member of the New York State board of medical examiners. to fill the vacancy caused by the death of Dr. A. R. Wright, of Buffalo.

Addition to a Hospital.—A structure four stories high, with a frontage of eighty-five feet and a depth of one hundred feet, is to be built as an addition to St. Mary's Hospital, Philadelphia, providing greatly increased accommodations.

Reform in Bake-Shops.—At a recent meeting of a labor union one of the delegates from the Bakers' Union lodged a complaint against a number of bake-shops which he said were in a filthy condition and a menace to the public health. He said that men and animals slept together in these bake-shops, and he asked the Union to request the board of health to make an investigation.

General Endowments.—By the will of the late Mahlon H. Dickinson, of Philadelphia, a member of the State board of charities, the sum of $5,000 each is bequeathed to the Children's Homeopathic Hospital of Philadelphia, the Pennsylvania Hospital, the German Hospital, the Episcopal Hospital, St. Mary's Hospital, and the Jewish Hospital, for the endowment of free beds in perpetuity.

Philadelphia County Medical Society.—At a stated meeting held March 28th, Dr. Mordecai Price exhibited a specimen from a case of perforative appendicitis, in which operation had been performed successfully. Dr. John G. Clark delivered an address entitled "The Anatomical Basis of the Menopause," illustrated by a lantern demonstration. He showed that the function of the ovaries depended largely upon their blood supply, and that the gradual destruction of ovisacs culminated in the menopause. Dr. James C. Wilson read a paper entitled "The Symptoms and Complications of the Menopause." Dr. John B. Chapin read a paper entitled "The Psychoses of the Menopause," in which he pointed out that the mental derangements that occurred in this connection did not differ essentially from those that occurred under other conditions. There was a mistaken notion that this period of life peculiarly predisposed to the occurrence of psychoses, but the actual evidence did not support this view. Such mental derangements might be expected at the menopause as would occur in predisposed persons in the presence of any other critical situation. Dr. J. M. Anders presented a paper entitled "The Cardiac Manifestations of the Menopause," referring especially to palpitation and tachycardia. Dr. F. X. Dercum made some remarks upon "The Neuroses of the Menopause," pointing out that this period was one at which neurotic disturbances were prone to occur, though not presenting any distinctive character. Dr. Judson Daland related a case in which periodical gastric disturbance occurred in a woman at the menopause. Dr. J. Madison Taylor suggested that nervous disturbances of the menopause might be more common in the leisure class than in those more humbly circumstanced.

Dr. Horner and Appendicitis.—On page 519 of the MEDICAL RECORD, March 24, 1900, under the heading "Medico-Surgical, Cr.," "Recoveries from interval operations" should read "Recoveries from operations advised by physicians in primary cases."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 31, 1900. March 27th.—Assistant Surgeon J. T. Kennedy ordered to additional duty at the marine recruiting rendezvous, San Francisco, Cal. March 29th.—Pharmacist J. F. Pearson appointed pharmacist from March 26th.

Dr. St. George Mivart died suddenly in London on April 1st. He was born in London in 1827. He was formerly lecturer on zoölogy at St. Mary's Hospital Medical School, and professor of biology at the University of Louvain. He was a doctor of medicine, but did not practise. He was recently excommunicated by the Roman Catholic archbishop of Westminster for asserting that to ask a reasonable man to believe such "puerile tales" as those of the Tower of Babel, of Jonah, and of the creation of the world in six actual days, was an insult to his intelligence. He was a fellow of the Royal, of the Linnæan, and the Zoölogical Society. Among his publications are "Genesis of Species," "Nature and Thought," "Types of Animal Life," "The Cat," "An Introduction to the Elements of Science," "Man and Apes," and "The Origin of Human Reason."

Obituary Notes.—DR. JOHN COOPER, of Brooklyn, died at the Seney Hospital on March 29th, of gangrene of the foot. He was born in London in 1815, and obtained the qualification of the Royal College of Surgeons in 1837. He became attached to the medical corps of the British army, and later settled in New South Wales, where he was a member of the medical board for several years. In 1846 he came to this country and began practice in Huntsville, Ala., where he remained twelve years, and then removed to Brooklyn.

DR. ALFRED E. JONES, of Brooklyn, died at the Home for Aged Men in that borough on March 30th. He was born in Lexington, Ky., in 1810.

DR. DAVID N. TAYLOR, of Amsterdam, N. Y., died on March 28th at the age of forty-four years. He was born in Albany and was graduated in medicine from the Long Island College Hospital Medical School in 1884.

Dr. William W. Rodman, of New Haven, died at his home in that city on March 30th, of acute bronchitis, at the age of eighty-three years. He was a graduate of the Jefferson Medical College in 1844.

Dr. Francis G. Warren died in Biddeford, Me., on April 2d, at the age of seventy-two years. He was a graduate of the Jefferson Medical College in 1861, and served during the civil war as surgeon of the Fifth Maine regiment.

Dr. Joseph H. Vondy died at his home in Jersey City on April 2d, at the age of seventy years, from pneumonia. He was born in Miramichi, N. B., and was graduated from the New York University Medical School in the class of 1851.

Dr. James Cummiskey died at Philadelphia of pneumonia on March 25th, aged sixty-four years. He was graduated from Jefferson Medical College in 1856, and was for many years physician in chief to St. Mary's Hospital.

Dr. Franklin B. Hazel died at Philadelphia on March 28th, at the age of fifty-four years. He was graduated from the medical department of the University of Pennsylvania in 1870.

Dr. Frank B. Keller died at Pottstown, Pa., on March 24th, from erysipelas and septicæmia, at the age of fifty-one years.

Dr. Edwin M. Smith died at Philadelphia on March 29th, aged seventy-seven years. He was graduated from Jefferson Medical College in 1846.

Progress of Medical Science

Medical News, March 31, 1900.

Myocarditis in Infancy and Childhood.—Henry Koplik states that the pathological anatomy of this condition has received most of its facts from autopsies upon infants and children dying of the infectious diseases. This affection is one of the most important conditions met with in the sick infant and child. The myocardium is peculiarly susceptible to the action of any toxin. Symptoms of functional cardiac disturbance may appear in the convalescence, not only of diphtheria, but of any severe throat disease of the streptococcus or staphylococcus variety. The writer then quotes cases showing the effects of malaria and pneumonia on the heart muscle, and then mentions the relations of pertussis and rheumatism to the heart. This organ must be carefully guarded, and depressing drugs should be cautiously used. The hope of these cases lies in well-sustained nutrition.

Uterine Fibroids Complicated by Pregnancy.—Willis E. Ford draws the following conclusions from several quoted cases. When the lower third of the uterus and the entire cervix are free from any neoplasm, the physician may safely await the result of the pregnancy, even if the fibroid is of considerable size. If a neoplasm of any considerable size is found opposite the internal os, especially if it is large enough to block in any way the birth canal, then the question as to waiting until the child is viable and doing a Cæsarean section, or whether a total hysterectomy must be done early, is determined by whether the fibroid is in the anterior or posterior wall of the uterus. The dangerous position of the fibroid is in the anterior wall of the uterus, low down.

Alcohol as a General Stimulant and Heart Tonic; its Use to the Animal Economy in Health and Disease.—T. J. Hillis believes that alcohol should never be given in lingering diseases, nor in convalescence from acute diseases, if it irritates or upsets the stomach. Alcohol should never be taken after eating. It cannot aid digestion, and so must retard it by its weight and bulk. Further, it precipitates the digestive ferments, coagulates the albuminoids, and often completely arrests the digestive process. The amount to be consumed varies with the individual and the circumstances. Alcohol is a form of food already digested, but it is not adapted to the normal wants of the body, and is indicated only at a time and under conditions which render the digestion and assimilation of other foods impossible.

A Case of Pneumohydrothorax with Great Permanent Displacement of the Heart.—Charles Ross Jackson quotes the case of a young man, seventeen years of age, in whom the cardiac impulse is present in the right fifth intercostal space in the nipple line. Dulness extends almost from the nipple line to about the right sternal border and upward to the third space. The past history is of a pain in the chest, which began about a year ago and became chronic. In an acute attack which followed, the perforation probably occurred, and pneumothorax developed. Creosote and tonics ameliorated these symptoms. The prognosis is unfavorable.

Toxins from a Chemical and Pathological Standpoint.—A. E. Austin quotes Gautier's description of the nature of toxins: "All infectious microbes act upon the organism by the poisonous products or toxins which they secrete. These poisonous products are chemical substances susceptible of filtration, precipitation, and resolution. These toxins are usually complex, made up of an alkaloidal material and a nitrogenous substance, which is very active. The primary effect of all these toxins is rise of temperature, and probably all fever is produced by the agency of some one of them." Austin then gives several methods of extraction.

The Treatment of Whooping-Cough.—Henry Coggeshall first cocainizes as much of the nasal mucous membrane as can be done by the use of a spray, followed by cotton-tipped probes wet with the solution; then an application of a two- or a four-per-cent. solution of nitrate of silver to the nose and naso-pharynx, to be followed by a mild alkaline and antiseptic wash by spray or by post-nasal douching. He also speaks of belladonna and suprarenal extract.

Journal of the Amer. Med. Association, March 31, 1900.

Observations in Laryngotomy; Tracheotomy; Intubations; Based on Clinical and Experimental Evidence.—George W. Crile says that for these experiments the animals were reduced to full surgical anæsthesia by ether, and were killed before recovery therefrom. The results of the tracheotomy experiments are of practical importance mainly in pointing out the very great safety of operative procedures, so far as the immediate results are concerned, on the trachea, as compared with like operations on the larynx. The intubation experiments show that the reflex inhibition is due to efferent impulses set up by mechanical irritation of the terminals of the superior laryngeal nerves. The author urges the necessity for a differential diagnosis between obstruction from membranes pushed down and the collapse from reflex inhibition. As to the prevention of collapse from reflex inhibition, so far as the heart is concerned, this is done by a preliminary hypodermic injection of atropine. Or the local application of cocaine on the laryngeal mucosa may prevent not only the reflex inhibition of the heart, but of the respiration as well.

Albuminuria.—Charles Alling Tuttle considers albuminuria from the point of view of its prognostic value in chronic nephritis. He says that the mass of evidence which has come to us of late from the autopsy table shows conclusively that chronic nephritis exists and is an unrecognized cause of death in a proportion of cases far beyond ordinary belief, and the comparison of carefully kept records of cases before death with autopsy findings shows that little reliance can be placed on the mere urinary examination, either positive or negative, as a means of absolute diagnosis or prognosis of Bright's disease. The writer's own experience leads him to believe that (1) Bright's disease may exist without the ordinary urinary manifestations, viz., albumin or casts; (2) albumin and casts may be found in the normal urine and do not necessarily mean Bright's disease; (3) given a case of chronic Bright's disease with albuminuria, the fact of its presence, its constancy, or its amount has absolutely no prognostic significance.

Notes on Fractures of the Long Bones without Deformity; the Sub-Periosteal Type of Fracture in the Young.—James Porter Fiske's conclusions are that (1) subperiosteal fractures usually present certain typical features which we should be able to recognize and differentiate from complete fractures; (2) their union is characterized by the formation of a slight amount of callus, and solid union takes place in much less time than in complete fracture; (3) in every contusion to the limbs in the young, no matter how slight, a systematic search should be made for this particular lesion; (4) in rickets there is a greater liability toward the occurrence of incomplete fracture; (5) many cases of subperiosteal fracture are undoubtedly converted into simple fracture through improper manipulation or by too forcible examination.

A Pathological Study of Eighty Tumors of the Mammary Gland, with Special Reference to the Occurrence of Malignancy.—Fritz Carleton Hyde gives the results of a microscopical analysis of eighty tumors of the breast, which he classifies according to their histological structure. The relative occurrence of the different varieties of the eighty cases is as follows: Carcinoma, 70; carcinoma medullare, 12.5; carcinoma simplex, 27.5; carcinoma colloides, 6.25; carcinoma scirrhosum, 12.5; adeno-carcinoma, 10; sarcoma, 7.5; tuberculosis, 3.75 per cent. Five per cent. not classified as carcinomata show carcinomatous proliferation. The writer concludes that it seems justifiable, from the microscopical examination only of these eighty cases, to state that there is no strictly benign tumor of the breast, and that the only rational treatment is complete removal as soon as discovered.

Are We Degenerating? If So, Why?—E. Stuver says the enormously increased percentage of the insane as compared with the whole population within the last twenty or thirty years is a strong proof that mental stability is not increasing, and that the spread of venereal diseases, tuberculosis, and carcinoma, together with the widespread use of stimulants and narcotics, has done much to taint the blood and lower the vital resistance of the people. Also that the intellectual faculties have been cultivated at the expense of the moral nature, with the result of asymmetric development.

A Physiological Consideration of the Food Value of Alcohol.—Frank Woodbury and Seneca Egbert, in considering the experiments of Professor Atwater, are forced to the conclusion that he has produced practically no evidence whatever to support the claim that alcohol is a wholesome or useful food, nor to change the generally accepted view that its physiological action on the human body is destructive and never constructive.

A Study in Anæsthesia.—Rosalie M. Ladova submits a record of one hundred and one cases of anæsthesia in which notes were taken as to the duration, pulse and respiration range, condition of the pupils, gastric irritation, how soon anæsthetized, how soon out, and the amount of the anæsthetic. The writer thinks it inconceivable that the idea of a trained anæsthetist in every hospital should gain ground so slowly.

The Interdependence of Physiology and Morphology, and their Educational Importance. — James Weir says biology should be taught in every school in the land, and that medical schools especially should establish biologic chairs, from which should be taught the great truths of physiology, morphology, and psychology.

Simple and Ethereal Sulphates.—G. W. McCaskey describes a simple and rapid method for the separate determination of these bodies, which, he says, are an indication of the intensity of bacterial processes. The principal compounds of this class of aromatic substances are phenol, indol, skatol, cresol, and pyrocatechin.

The Humane Side of Warfare.—N. Senn says that war is gradually becoming more humane, a result largely contributed to by the Geneva Convention. He gives some personal experiences from the Santiago campaign.

Boston Medical and Surgical Journal, March 29, 1900.

Typhoid Spine.—R. W. Lovett reports a case of muscular rigidity, excessive pain in the lumbar region, tenderness of the spine, and pain referred to the peripheral end of the nerves, following typhoid fever. The tuberculin test was negative. The Widal test was positive. Recovery followed in less than a year. The typhoid bacillus has frequently been found in bone marrow. The author holds that, reasoning from the analogy of other post-typhoidal bone lesions, we may conclude that an osteomyelitis, or possibly periostitis, of the vertebræ is present in some of the cases which have been supposed to belong in the neurotic class of typhoid spines.

Idiopathic Pneumohæmothorax with Recovery after Aspiration.—Elisha S. Boland describes a case which he calls idiopathic, because to all appearance there was no objective or subjective evidence of pre-existing trouble. The case suggests: (1) That we can have (practically) a primary pneumohæmothorax; (2) that without diagnostic aspiration we cannot be sure of the nature of any pleural effusion; (3) that aspiration may precipitate an influx of air into the pleural cavity, even if the lung is not touched by the needle; (4) that the pleural cavity can unaided take care of aseptic blood as well as of air.

The Open or Operative Treatment of Fresh Fractures; is it Ever Justifiable?—Charles L. Scudder concludes from the previous number an article which is the result of an analysis of one hundred and fifty-three cases of fracture of the lower extremity. The ideal result to be aimed at is union of the fracture without deformity or impairment of the function of the limb. The usual methods are often unsatisfactory. Anæsthesia and the *x*-ray afford the means of accurate diagnosis. Sepsis is practically abolished.

Closed fractures can safely be treated by open incision when other methods fail to secure reduction and immobilization.

Bradycardia, with Intermittent Albuminuria.—Andrew H. Whitridge reports a case in which there was a period of permanent bradycardia of three months, with intermittent albuminuria of over two years' duration. The etiological factors were probably occlusion of the coronary arteries, Bright's disease, and irritation caused by the removal of a lipoma of the neck, causing stimulus to the vagus nerve.

New York Medical Journal, March 31, 1900.

Report of a Case of Tumor of the Cerebellum with Drainage of Fluid through the Nose.—The case of a young woman, aged twenty years, is reported by G. W. McCaskey. Her history, which began after an attack of the grippe, extended over three years, the diagnosis being an inoperable tumor at the base of the brain located in or adjoining the pons on the left side. Autopsy showed the tumor to be a mixed angeioma, having an apparent origin from the anterior margin of the left lobe of the cerebellum. About two months before death the patient began to have a daily serous discharge from the right naris amounting to several ounces. At times the discharge was so profuse as to threaten strangulation. Another curious feature was that the escape of the fluid was followed by a partial restoration of hearing, which for three months had been in complete abeyance.

Spontaneous Discharge of Cerebro-Spinal Fluid from the Nose.—W. Freudenthal reports the case of a woman, aged fifty years, who had for over a year a dropping from the nose. The amount was increased when the head was bent forward. Examination of the discharge showed a watery appearance, with alkaline reaction, and a specific gravity of 1.007 +. The results of chemical analysis seemed to prove beyond a doubt that it was cerebro-spinal fluid. There were loss of smell, nasal polypi, and chronic otitis media. The general nervous condition was one of blunting of mental activity. The author discusses the literature of this class of cases, about which so little is known. Stoppage of the flow seems to excite the cerebral symptoms. Concerning treatment we know nothing, nor has any satisfactory theory of causation yet been established.

Arthritis Deformans and the Benefits of Electrical Treatment.—M. A. Cleaves gives the clinical histories of two cases. One was treated with Franklinic current, negative insulation, convective discharge with crown electrode for ten minutes, and with the brush electrode to the entire general surface (nutritional), localized to the affected joints (pain and disability). This patient was a laundress, aged fifty-one years. The other patient, a typewriter, aged nineteen years, received a continuous current bath, active contact, body immersed in decinormal salt solution in an insulated porcelain tub. Results in both cases were excellent.

Diabetes Mellitus with Special Reference to the Treatment with the Double Bromide of Gold and Arsenic.—G. D. Barney dilates upon the efficacy of this combination in the treatment of diabetes mellitus. He believes that it affects the nervous system, restoring the integrity of the glycogenic centre. It acts also as a powerful vasomotor regulator, increasing the vascular tone and diminishing the amount of blood supplied to the liver. It improves the digestion and the blood state itself. Clinical tables from three cases are given showing effects as measured by reduction of sugar and increase of hæmoglobin.

Leucocytosis.—J. H. Burch states that nearly all inflammatory and infectious diseases are characterized by leucocytosis, the exceptions being typhoid, measles, grippe, malaria, and tuberculosis. The author gives the results of blood tests made in pneumonia, typhoid, and tuberculosis, his findings being the same as already noted by other observers. He gives, as a fairly accurate average of the normal relationship of the leucocytes, the following figures: Two polymorphonuclear leucocytes to each microscopic field, one small lymphocyte to every five fields, one large lymphocyte to ten fields, and one eosinophile to twenty fields.

Is there a Rheumatic Periostitis?—Basing his opinion on the literature of the subject and one personal case, A. Stern believes that we have a true periostitis as the result of the rheumatic poison. In a boy aged ten years, who had had scarlatina and measles, upon the subsidence of the latter the joints began to swell, but were promptly relieved by the salicylates. Later a painful spot developed on the sternum, followed by swelling in various joints, also relieved by the salicylates. Gradual recovery supervened; but later a heart murmur appeared, with chorea.

Philadelphia Medical Journal, March 31, 1900.

A Case of Poliencephalitis in an Adult.—De Witt H. Sherman and William G. Spiller report a case of this nature in a medical student, twenty-one years old. There was no history of mental or nervous disease in the family, and the patient's previous history was good. The disease presented the clinical picture of Landry's paralysis, and terminated fatally in thirty-eight hours after the appearance of the first definite symptoms of motor disturbance. From a study of the clinical symptoms and the autopsical findings, the conclusions are arrived at that (1) Landry's paralysis may be due to poliomyelitis; (2) the latter is an infectious disease, the inflammation being greatest in the anterior horns, but occurring also in the posterior horns, the white matter, and the meninges; (3) the symptoms are motor in type, because the disease is especially of the anterior horns; (4) meningitis is not uncommon in poliomyelitis; (5) poliomyelitis in the adult is essentially the same disease as poliomyelitis in the child; (6) it is related pathologically to the non-purulent form of encephalitis and to the poliencephalitis of Wernicke.

The Inaccuracies of Home Modification of Cow's Milk.—Charles E. Woodruff discusses the difficulties of modifying milk accurately at home: 1. To be accurate, we must know the exact composition of the ingredients, which is impossible outside of a laboratory. 2. Extreme accuracy does not seem to be so necessary as we have been taught. 3. Women are so inaccurate in their methods that the specific directions of the physician are not carried out. 4. Infants vary so much that one cannot tell beforehand what any individual one will like. 5. Specialists are not agreed as to the proportions of proteids, fats, and sugar to use.

The Prevalence and the Diagnosis of Leukæmia.—George Dock gives the statistics of this disease, which lead him to think it is more common in Ann Arbor than in Germany. The diagnosis is difficult, and can rarely be made except by a blood examination. Pallor is not always present at first, but shortness of breath is common. The splenic tumor almost always has the characteristic sharp edge on the right side, and the anterior surface is large, smooth or broadly curved, and firm to the touch. Notches on the edge are not always found in a leukæmic spleen. Pain is almost invariably present.

Research into the Cause of Collapse or Death from Blows upon the Lower Chest and the Epigastrium.—George W. Crile concludes from animal experiments that the solar plexus may be disregarded as a factor in these cases, and that the cause of the collapse or death is the mechanical violence exerted either upon the heart muscle itself or its nerve mechanism. Collapse may be caused entirely independently of the vagi, though injury to these nerves probably contributes slightly to the result in most cases.

An Unexplainable Congestion and Enlargement of the Left Arm Cured by an Exploratory Operation; Splenectomy.—Orville Horwitz reports these cases. The first one occurred in a man, age not stated. The operation consisted in exposing the subclavian artery and vein and exploring the axilla. Nothing abnormal was found. The second case was in a woman, thirty-five years old, who had a splenic tumor weighing nine pounds. The patient died on the fourth day after operation.

A Case of Membranous Non-Diphtheritic Croup with Recurring Laryngeal Stenosis.—Herman B. Sheffield reports a case of this kind in a child two and one-third years old. The dyspnœa was relieved by intubation. Repeated cultures revealed no Klebs-Loeffler bacilli.

British Medical Journal, March 24, 1900.

A New Method of Performing Perineal Prostatectomy.—In describing his operation, P. J. Freyer says that, while advantage is taken of the perineal incision recommended by Dittel, Nicoll's object is attained by a much less heroic and dangerous proceeding than suprapubic cystotomy, namely, by a preliminary perineal opening into the urethra. The advantages claimed are: (1) The preliminary external urethrotomy permits of the introduction of the finger into the bladder, which, with a finger in the rectum, enables the surgeon to define accurately the shape, density, size, and extent of the prostatic growth. (2) The finger can be hooked over the enlarged lateral lobe and the latter pushed well into the ischio-rectal wound, thus to a large extent obviating a deep and dangerous dissection. (3) With the tumor pushed well into the wound, the capsule is easily incised and erased, and the cutting forceps and scissors are easily applied. (4) The finger in the bladder enables the surgeon to feel when the cutting instruments are approaching that viscus, so that he can remove the whole growth, except a thin layer for the support of the mucous membrane of the bladder and prostatic urethra. (5) The tube inserted into the urethral wound carries off all the urine, and prevents the perineal wound from becoming septic.

Vomiting Considered from Some of its Surgical Aspects.—William H. Bennett limits his observations to two classes of vomiting: (1) Vomiting occurring in connection with operations; (2) feculent vomiting, which is sometimes curative. With regard to the first, he says that when there is any possibility of the stomach being a reservoir for offensive material or half-digested food, the proper practice is to adopt stomach lavage, in order to prevent the possibility of lung implication from the passage of portions of the contents of the viscus down the trachea. As to the second point, the author concludes that in cases of abdominal disease or injury feculent vomiting as such is no positive indication for surgical interference, unless it is accompanied by increasing abdominal distention.

Punctured Wound of the Skull with Escape of Brain Substance.—William Odell reports a case of a child, aged sixteen months, who fell, piercing its head with a carpenter's gouge. After the child had recovered from the shock, which lasted till the second day, there was no rise of temperature or apparent constitutional disturbance. The child now seems perfectly well, has no squint, and its intellectual progress has been maintained.

Gastric Ulcer in Pregnancy and Hysteria.—J. W. McIntosh reports a case of a primipara (sixth month), in whom characteristic symptoms of gastric ulcer were present, including paroxysms of pain, vomiting, and hæmatemesis. Rest in bed, lavage, medication, abstinence from food for thirty-six hours, followed by a very gradual restoration of diet brought about a return to her normal condition.

A Case of Smallpox during Pregnancy.—In this case, reported by A. Dean Roberts, the disease resulted in premature labor. The only ill symptom was extreme weakness. The strength was maintained with plenty of liquid nourishment, and the patient made an uninterrupted recovery. She had been successfully vaccinated as a child, which probably saved her life by mitigating the severity of the disease.

When is Cancer Cured?—E. T. Fison reports a case of mammary cancer. The patient is now seventy years of age. Twenty-five years ago the left breast was removed; immunity existed for fifteen years, and recurrence took place ten years ago, yet the patient is still living.

Kernig's Symptom in Meningitis.—James Barr quotes several cases in which Kernig's sign occurred in the upper as well as the lower extremities, and says that he does not consider the sign necessarily diagnostic of cerebro-spinal meningitis.

The Lancet, March 24, 1900.

The Typhoid Bacillus and Typhoid Fever.—P. Horton-Smith gives a general description of the bacillus and enumerates its culture reactions. He believes that there is no proof as yet that the bacillus can multiply outside the human body. It has, however, great power of resisting the effect of desiccation, and hence may cause disease a long time after the original infection has existed. It produces a weak toxin. Further points in the lecture discuss the relative frequency of the germ in the different bodily organs, the eruption, the excretions, etc. We can no longer look on the disease merely as affecting the alimentary canal. It is rather a modified septicæmia.

Practical Observations on Cancer of the Breast.—W. M. Banks, in the second of the Lettsomian lectures, mentions the fact that these growths are frequently without pain, cachexia, nipple retraction, and other clinical manifestations generally spoken of as characteristic of the affection. Cancer may be simulated by chronic mastitis, small chronic abscess, small fibro-adenoma, and small, very tight, simple cyst. Special mention is made of acute mania after operations for removal. Finally the author calls attention to chronic interstitial mastitis, which, he thinks, is liable to become carcinomatous.

The Surgery of the Stomach.—A. Mayo Robson discusses dilatation and atony, due to various general and local causes, and persisting after the original cause has disappeared. He gives a statistical table of gastroplication (gastrorrhaphy), speaks of acute gastric dilatation, and describes gastro-enterostomy, tetany and tetanoid spasms in association with gastric dilatation, injury to the stomach, and finally cancer and other tumors of this organ. The lecture closes with statistical tables of the various surgical procedures.

Phosphatic Diabetes.—G. Rankin calls attention to a form of phosphaturia in which the urine contains excess of phosphate of lime, is of low gravity, and later may contain albumin and sugar. The patient complains of thirst, polyuria, and languor. Later symptoms are those of the diabetic coma type. No treatment is of avail, though buttermilk seems to have given some relief.

A Case of Irreducible Dislocation at the Elbow.—H. H. Russell describes this case, which was the result of a football accident in a boy of eight years. Both bones were dislocated backward. Reduction under chloroform was impossible, and an operation was performed. The eventual result was good.

On the Influence of the Temperature of Liquid Air on Bacteria.—A. Macfadyen's experiments show that bacteria may be cooled down to −190° C. for a period of twenty hours without losing any of their vital properties.

Note on the Causation of Cancer.—J. Sawyer attributes the increase of cancer in England to the increasing consumption of fresh meat, which is relatively undercooked.

Medical Press and Circular, March 21, 1900.

General Paralysis of the Insane.—Fletcher Beach says causes are physical and moral; the chief physical ones are excesses, syphilis, cranial injury, and heredity. Among moral causes are anxiety, prolonged intellectual labor, etc. The most common moral symptom is perversion of moral sense; another is irritability, or loss of determination. Intellectual change is the next most important symptom; absent-mindedness, loss of memory, mental confusion, inability to make calculation; sometimes hypochondriasis. The disease almost always ends in death. The diagnosis is from syringomyelia, diphtheritic paralysis, multiple peripheral neuritis, disseminated sclerosis, and bulbar paralysis. The patient in whom premonitory signs appear should be sent to the country. If there is excitability, bromides should be given, and especially if there are epileptic seizures.

The Influence of Heredity on Disease.—Hamilton says there are two theories, Darwin's of pangenesis and Weissmann's of the germ plasm. Tuberculosis is now believed by most pathologists not to be hereditary and seldom to be congenital. Of all diseases the neuroses are the most markedly hereditary. Syphilis is not regarded as an hereditary disease, while hæmophilia is eminently so. Since it is transmitted to males along the female line, it might bear some analogy to menstruation. There is no evidence that diseases due to external agencies can be transmitted. Hereditary tendencies to disease occur as variations of the germ plasm. These variations arose far back in the history of the race, and have been perpetuated, or may recur atavistically. There is little evidence of the importance of maternal impressions. Telegony may prevail in the case of hereditary disease.

Contributions to the Topical Diagnosis of Cerebral Disease.—H. Oppenheim reports a number of cases. After a fall on the head, there was dulness of intellect, sensory and amnesic aphasia, alexia, agraphia. Tumor of the left hemisphere was assumed, extending to the large ganglia and to the gyrus fornicatus. Trephining and evacuation of fluid gave temporary improvement, but after death a tumor was found as suspected. Other cases are given. After convulsions a patient became blind. At autopsy a tumor in the cerebellum was found compressing the left hemisphere. A case of carcinoma metastasis to the brain is mentioned.

Cases of Skin Diseases Presenting Unusual Features.—Arthur Hall found the frequent application of rectified spirits, with a little menthol added, useful in cases of lupus erythematosus. Parakeratosis palmaris was treated with pumice stone and salicylic-soap plaster. A spreading ulcer at the root of the nose proved fatal in an infant. A recurrent ringed vesiculo-bullous eruption in children is mentioned. An erythema induratum in a young woman had recurred each autumn for four years, lasting through the winter. Sherwell's treatment for scabies is recommended.

Berliner klinische Wochenschrift, March 12, 1900.

Glass-Blower's Mouth and its Complications.—Scheele calls attention to a dilatation of Steno's duct and consequent parotid symptoms from the enormous pressure exerted in the anterior oral cavity from glass-blowing. Players on wind instruments are not subject to the lesion, for in them the air pressure comes from the back of the pharynx, and the anterior oral cavity becomes a mere conduit for the air. He makes the suggestion that it may become possible by a suitable mechanical device to employ compressed air in glass-blowing, instead of using the breath as is now done.

Pathogenesis and Therapy of the So-Called Anal Fissure.—C. Rosenbach finds the most common cause of the affection to be a disturbed innervation of the muscular apparatus of the lower bowel, as a result of which the rectal sphincter does not relax from various forms of irritation, while the muscular fibre higher up continues to contract. This causes a great strain on the rectal mucosa, producing partial or complete rupture of the same and the fissure formation. He recommends digital manipulation of the lower rectum, with the later use of the soft tube and irrigation.

South Africa; its Prevalent Diseases and Sanitary Conditions.—W. Kolle describes the geography and climatic conditions of the country and the organizations of the various departments of health in the different sections. He then calls special attention to typhoid, dysentery, smallpox, syphilis, and other affections as seen in this part of the world. Tuberculosis is not an indigenous disease, and most of what there is has been introduced by foreigners. He also briefly describes some of the affections peculiar to this region.

Wiener klinische Wochenschrift, March 8, 1900.

The Radiographic Appearance of the Normal Thoracic Aorta.—G. Holzknecht states that the result of both sagittal trans-illuminations from before back, and *vice versa*, is that no part of the thoracic aorta is visible as a distinct shadow in the picture, but the whole normal thoracic aorta is covered by the middle shadow. The trans-illumination in the frontal direction can be made from right to left, and *vice versa*. The most valuable trans-illuminations for the estimation of the condition of the aorta, next to the sagittal method discussed in the beginning, are the four following: The direction of the projection is, oblique through the thorax: (1) From left back to right front; (2) from right front to left back; (3) from left front to right back; (4) from right back to left front. The frontal plane of the patient is in every case brought to an angle of 45° with the direction of the rays.

A Case of Congenital Stenosing Hypertrophy of the Pylorus.—Franz Hansy reports a case of this kind which is comparatively rare, and which does not commonly present itself for operation. It is certain from the observations made during the operation that the case is one of congenital hypertrophy of the pylorus, which has resulted in relative stenosis of the pylorus, and that has led gradually to a decided dilatation of the stomach. There is no question about the correct treatment: gastro-enterostomy in front of or behind the colon with the Murphy button or suture, according to the nature of the case, should be performed.

Contribution to the Biology of the Malarial Parasite.—Xaver Lewkowicz says that there are clinical grounds for assuming that in cases of intermittent fever at long intervals—twenty-three-day type—it takes the crescents twenty-two days to develop. The benign tertian, the twenty-three-day type, and the malignant tertian are due to the same polymorphous parasite. All of these forms are due to mosquito inoculation.

Münchener medicinische Wochenschrift, March 20, 1900.

Upon the Indications for Operation in Appendicitis.—Adolf Schmitt takes up the recent statement of Gossman that in Munich operation is too infrequently undertaken, and considers the question from the standpoint of hospital cases, which are getting more frequent because the indications for operation are becoming each year more clearly defined. Operation is imperative in large peri- and paratyphlitic abscesses. The course of treatment is most difficult to decide in the great majority of cases. The attack itself is usually recovered from under expectant treatment, but the underlying condition remains, predisposing to recurrence. Internal treatment and surgery should here go hand-in-hand. The indications and operative measures are considered *in extenso*.

A Serious Danger from Faulty Injections in Gonorrhœa.—From a reliable source is published an account of severe complications extending over a period of nine months following a gonorrhœa treated by injections of zinc. There were besides epididymitis, prostatitis, etc., large abscesses and vesico-rectal fistula necessitating operations. It was discovered too late that the acorn-pointed syringe had been inserted within the lips of a phimosed prepuce, and the injection made so that the preputial sac had been distended and the smegma probably washed at different times into the canal, aided by manipulations carried out by the patient to make the fluid penetrate.

A Case of Acute Cocaine Poisoning.—Dr. Bergmann gave a cocaine injection of 5 cgm. of the drug for the relief of severe pain. Within five minutes the pain had all disappeared. The next day 3 cgm. only were injected, when within three minutes there was a faint feeling, with collapse, followed by rapid heart action and respiration; after ten minutes clonic contractions occurred, with widened pupil, bulging globes, and other severe symptoms. These all passed off, and by the next day the man was out. The pain, which had been of long standing in the region of the hip joint, did not return.

Experiments with Alcohol as a Local Application in Gynæcology.—Ludwig Seitz cites instances of chronic metritis, gonorrhœal infections, etc., in which the local use of alcohol has been tried, and concludes that, with the exception perhaps of tuberculous processes in the peritoneum, the results are not very encouraging. In one case only of chronic endometritis and metritis, with excessive secretion, was the action favorable. The power of abstracting fluid from the tissues may make alcohol useful in such cases, and in tuberculous peritonitis it should have further trial.

Hemorrhoidal Nodes in Earliest Childhood.—Dr. Burwinkel says the books teach that hemorrhoidal nodes are among the rarest observations. He relates the case of a girl about two years of age, who soon after birth showed this condition, which after eleven months of general treatment disappeared. He attributes their occurrence largely to the lack of submucous fat deposit about the rectum, due to a general marasmic state.

Flexible Aluminum Splints.—Dr. Steudel already in 1896 recommended pliable aluminum for splints. The bending apparatus has been improved, as shown in an illustration, while other figures show its mode of employment at the bedside. The price in the various widths is quite moderate.

Bulletin de l'Académie de Médecine, March 6, 1900.

Dysenteric Abscess of the Liver.—M. Kelsch and M. Minier hold that in the light of modern pathological findings hepatitis and dysentery are alike in their elementary lesion, which is a necrosis, differing in course only by reason of the difference of structure in liver and intestines.

Treatment of Obesity.—G. M. Debove treats obesity by a diet unmodified by cooking or preserving, such as raw milk, eggs, meat, salads, and fruits. He reports the case of a man whose weight after less than a year of treatment was reduced from 148 to 93 kgm. (325 to 204 pounds).

French Journals.

Symptoms and Pathogeny of Isolated Paralysis of the Great Denticulated Muscle.—A. Souques adds some new cases to the short list in which the serratus magnus has alone been implicated in paralysis. The signs vary with examination in repose and when the arm is voluntarily raised. The opinions of various observers are given. The truth, he thinks, lies between the extreme views of Duchenne and of Berger, and that there is moderate displacement of the scapula, which may escape superficial examination. To the sixteen cases collected by Barreiro he adds one of his own and two found in literature, and studies them together. He advances the theory that the paralysis is consecutive to sudden violent effort. It occurs almost always in men and upon the right side. In one case, involving the left, it was found that the man was left-handed.—*Gazette des Hôpitaux*, March 17, 1900.

Treatment of Muco-Membranous Entero-Colitis.—G. Lyon concludes his paper, discussing the injection of large quantities of oil in spasm of the intestines; various sedatives, prolonged baths, thermal treatment, painful paroxysmal crises, febrile forms, and treatment in infantile forms, etc.—*Revue de Thérapeutique Médico-Chirurgicale*, March 15, 1900.

The Necessity of Stomach Lavage Preceding Gastro-Enterostomy.—René Belin concludes that whatever may be the condition of fatigue of the patient, it is indispensable in interventions for pyloric affections, contractions, or cancers, to place lavage of the stomach at the head of the list of the necessary precautions before operation.—*Le Progrès Médical*, March 17, 1900.

International Medical Magazine, March, 1900.

Tuberculosis of the Nervous System.—D. J. McCarthy states that in this field there must be differentiated those processes in which the tubercle bacillus itself is the causative factor, and those in which poisons produced by tuberculous processes elsewhere in the body are at fault. He then speaks of the different varieties of tuberculosis of the nervous system.

Tuberculin, Anti-Tuberculin, and Anti-Tubercle Serums.—Joseph McFarland says that tuberculin is prepared from the fully-grown cultures by a process of concentration. He then speaks of progressive administration of tuberculin to animals and the development of an anti-tuberculin. He mentions the anti-tubercle serums of different investigators.

Diagnosis and Treatment of Tuberculosis of Bones and Joints.—De Forest Willard states that this diagnosis when the disease comes from acute osteomyelitis or epiphysitis is usually readily determined by the sudden onset of these latter conditions with extreme pain, and the rapidity with which they advance to destruction of bone and suppuration.

The Treatment of Pulmonary Tuberculosis.—S. Edwin Solly believes that the great defect in the treatment of tuberculosis is the time of its application. The tuberculous as a rule do best in high climates which are sunny, but in which the air is dry and cool rather than warm.

Tuberculosis of the Skin.—Jay F. Schamberg speaks of tuberculous ulcerations of the skin (tuberculosis cutis orificialis), anatomical tubercle (tuberculosis verrucosa cutis), scrofuloderma, and lupus vulgaris. In all of these affections the tubercle bacillus may be found in the skin.

Tuberculous Ulcerations in the Stomach and Intestines; the Use of Tuberculin.—Boardman Reed declares that as far as his experience goes in the use of tuberculin for tuberculosis of the stomach and intestines, the remedy is perfectly safe in proper doses, and is curative when there is no septic complication.

The Treatment of Consumption.—W. Blair Stewart advises fresh air, as perfect hygienic surroundings as possible, a careful diet, and exercise. He approves of the use of guaiacol carbonate, strychnine, capsicum, and quinine—also belladonna or codeine if sweating and cough are bad.

The Laboratory Diagnosis of Tuberculosis of the Urinary System.—W. Wayne Babcock advises the necessity of greatest cleanliness in this manipulation. It is well also to examine the urine immediately after it has been voided.

Annals of Gynæcology and Pediatry, February, 1900.

Intra-Abdominal Adhesions.—A. L. Beahan states that operative procedures have taught us all we know regarding abdominal adhesions. It is possible that they bear close relations as a factor to the production of malignant disease. Their prevention requires that all raw surfaces be covered and possibly dusted with powder; that bleeding be checked and oozing be stopped; while open treatment with drainage completes the toilet. Drained cases are always safest and least painful.

Tolerance of the Gravid Uterus, with a Case.—H. C. Young cites the case of a woman, thirty-five years old, who on becoming pregnant had a convulsion about five weeks after conception. The cervix was painted with tincture of iodine, and later dilated several times with the introduction of bougies. Finally, all measures failing to give relief, or to cause expulsion of the fœtus, the cervix was manually dilated and the fœtus delivered.

Exploration of the Abdomen as an Adjunct to Every Cœliotomy.—Howard A. Kelly states that there are three classes of cases to which this examination may be applied: (1) When it is made simply as a routine procedure; (2) when, on opening the abdomen, contrary to expectation no disease is found near at hand; (3) when the disease operated on is probably complicated by the affection of some other organ.

Notes on the X-Ray; its Usefulness and Mistakes.—J. Rudis-Jicinsky describes the usefulness of the *x*-ray in the detection and diagnostication of fractures and dislocations. Calculi and encapsulated trichinæ may sometimes be seen. Chest affections without physical signs may be diagnosticated. The manipulator must know "how to read the shadows," in order to avoid mistakes.

Oöphorectomy for Gross Functional Nervous Diseases Occurring during Menstruation.—D. C. Brockman, after reporting four cases of this nature, says that it is only by patient, painstaking work along this line, with the careful experience of three or four years, that we shall learn on what cases to operate, and what not to treat surgically.

Obstetrical Prophylaxis in Gynæcology.—James Clifton Edgar affirms that a large proportion of cases that apply to the gynæcologist for relief of crippled pelvic organs owe their condition to mismanagement or avoidable accidents of the pregnant, parturient, and lying-in states.

Meddlesome Gynæcology.—Herman E. Hayd believes that, in spite of the cry that too much operating is done nowadays, most of the symptom-producing definite and discoverable lesions in women are cured best and quickest by operative measures.

How to Prevent and How to Treat Ununited Fractures.—A. C. Bernays says that non-union can always be prevented by proper approximation and immobilization, in the absence of a constitutional vice.

Illinois Medical Journal, March, 1900.

A Mechanical Method of Treating Sciatica.—C. C. Hunt advocates the use of the Hodgen splint, which prevents movements which are the result of the action of muscles of the hip and thigh over which the great sciatic nerve presides, but scarcely interferes at all with passive motion, especially at the hip joint. The patient can move from one side of the bed to the other, or turn slightly on the opposite side, and the toilet of bed and body can be arranged with little discomfort. In about sixty cases treated by the author pain was relieved in from one to six hours after the splint was adjusted, and in two weeks practical cure resulted.

The Medico-Legal Aspect of Bright's Disease.—Columbus Barlow believes that if the cerebral symptoms in cases of nephritis are marked, the patient's mental capacity should be tested before he is allowed to make a will.

Why and When to Operate for Appendicitis.—W. F. Grinstead believes in treating a first and second attack of catarrhal appendicitis medically, and in an interval operation after a second attack.

Diagnosis and Clinical Course of Puerperal Eclampsia.—Frank B. Earle attaches much importance to severe frontal or unilateral headache, associated with insomnia, as one of the earliest symptoms of eclampsia.

An Unusual Case of Perforating Gastric Ulcer.—C. W. Hall reports a case of four severe gastric ulcers without any history of gastric disturbance.

Two Affections of the Knee Joint.—George N. Kreider reports a case of gonorrhœal synovitis and one of loose body in the joint.

University Medical Magazine, March, 1900.

Absorption and Metabolism in Exclusive Rectal Feeding.—D. L. Edsall narrates his experience with enemata in a case of gastric ulcer occurring in a housemaid who was under close observation for a considerable time. The enemata consisted of 250 c.c. of peptonized milk with the yolks of two eggs, given three times daily, and in each instance being preceded by a cleansing enema of plain water. Results were most satisfactory. Edsall calls attention to the fact that the mere retention of rectal enemata is no sufficient evidence that the patient is being properly nourished by them.

Report of the More Interesting Cases in a Month's Service in the University Maternity.—By A. H. Remington. The following were reported: Cæsarean section; abdominal section for extra-uterine pregnancy or sepsis following abortion; the same for appendicitis complicating pregnancy and the puerperium; the same for streptococcic infection and an enormous necrotic ulceration of the caput coli, and the same for late infection in the puerperium; two cases of primary repair of lacerated cervix.

On the Use of Antitoxin in Diphtheria with Special Reference to Small Doses.—J. H. Musser employs in children up to six or eight years an initial dose of 500 units, to be repeated at intervals of six hours if the fever does not fall, if the strength of the patient does not improve, or if the local manifestations are spreading. For children over eight years, 1,000 units are given as an initial dose, and this is repeated at intervals of eight to twelve hours as needed.

The Fertilization of the Egg and Early Differentiation of the Embryo.—By F. G. Conklin. A paper read before the University of Pennsylvania Medical Society, February 16, 1900.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

More Remarkable Recoveries from Bullet Wounds.—The remarkable recoveries from bullet wounds which Sir William MacCormac and Mr. Frederick Treves, the principal civilian surgeons serving as consultants with the British forces, have already recorded, still continue. Sir William MacCormac sends the notes of twenty cases to *The Lancet*, which had been brought under his notice since his publication of the series which I have already quoted to you, and I can only echo his astonishment at the favorable results of treatment. Among other cases he mentions the following:

An officer received a shell wound in the head, five inches long by three inches at the widest part, the skull being exposed over the mastoid process. He was also shot transversely through the back at the level of the ninth dorsal vertebra. Within three weeks the wounds were practically healed, and the paralysis of the lower limbs which was at first present disappeared.

A bullet entered the skull in another case just outside and slightly above the left ala nasi, and emerged behind the tip of the right mastoid process. There were copious epistaxis and deafness of the right ear. The wounds healed at once, and the man is quite well, though the deafness persists.

A bullet in a third case entered the sternum at the junction of the manubrium with the gladiolus, and emerged just external to the juncture of the right arm with the thorax posteriorly. There was hæmoptysis, but the wounds healed without pulmonary trouble, though neuralgia of the arm and wrist-drop ensued.

Another patient, a colonel, was wounded by a shrapnel bullet which entered one inch below the spine of the left scapula. It was cut out beneath the skin one inch to the right of the xiphoid cartilage. In this case also there were hæmoptysis and symptoms of nerve-lesions in the arm, but no pulmonary trouble.

An officer was shot beneath the outer end of the right clavicle, the bullet emerging just to the left of the spine of the fifth dorsal vertebra. Cough, hæmoptysis, and dyspnœa gradually gave way to convalescence.

A bullet in another case entered at the inner end of the fifth right intercostal space close to the sternum, and emerged half an inch below the twelfth right rib, and two and a half inches from the middle line of the back. There was hæmaturia, which subsided, and the patient recovered with no further symptoms.

In the case of a private wounded at an unknown range, the bullet after traversing the left arm entered the thorax one and a half inches internal to the left nipple, and emerged through the trapezius muscle at the level of the spine of the sixth cervical vertebra, two inches to the right of the middle line. There was hæmoptysis, which ceased, and the wounds healed without any untoward symptoms.

In another case the bullet entered at the eighth right intercostal space in the mid-axillary line and emerged half an inch above and two inches posterior to the left anterior superior spine of the ilium. The patient vomited after the injury, but recovered without further symptoms.

These eight cases are perhaps the most astonishing of Sir William MacCormac's latest series, but several of the others are nearly as wonderful. There can be no doubt that in the cases I have briefly noticed tremendous injuries must have occurred—injuries of the sort that until recently surgeons have considered fatal—with no disastrous sequels. In the last case the bullet must have traversed the liver and probably the intestine; in the case preceding it the escape of the big vessels is marvellous, while the lung must have been wounded; and in the case recorded before that the kidney was clearly injured. Perforating wounds of the skull, abdomen, and thorax, if made with a Mauser bullet, appear to have no particular terrors.

Mr. E. L. Acutt, a Durban resident, has given to the British hospitals one hundred and fifty portable and comfortable sick-beds. They are distributed between the hospitals at Frere, Chieveley, and Estcourt, and have been immensely appreciated by the wounded. Mr. Acutt also offered to equip and maintain at his own expense a hospital of one hundred beds, but in view of the large amount of voluntary aid received by the British in this direction the principal medical officer did not consider it necessary to accept the offer. Mr. Acutt has certainly done as much as any one citizen could be expected to do without maintaining a hospital at his private expense; but the authorities at the Cape and the organizers of charity in England ought to make their stories agree. The Duchess of Montrose has quite recently appealed to Scottish residents in London for subscriptions, on the ground that the army medical department has stated that "further hospital accommodation is greatly needed for the troops in South Africa."

Dr. Conan Doyle has started for South Africa to act upon the staff of the Langman Hospital. If Dr. Doyle can put into practice just those marvellous qualities of patience, discrimination, and keen observation with which he endowed his popular hero, what an ideal scout he would make! I do not suggest that such qualities are thrown away upon medical work, for medical work may be described as scouting to find out where pathological foes are lurking and threatening; but it is a noteworthy thing that Sherlock Holmes should have been selected by Colonel Baden-Powell, the defender of Mafeking, in his recent pamphlet upon scouting, as the type of man required as a scout, and that now Sherlock Holmes' creator should be gone to the seat of war. It is rather a long time, I believe, since Dr. Doyle was occupied in practical medicine, while he has been using his faculties of imagination and intuition unceasingly; and I am tempted to suggest—without conveying the least reflection upon the medical novelist's therapeutic skill—that he should be allowed out scouting.

Miss Mary Kingsley, the celebrated traveller in South Africa, has arrived in Africa as a nurse. She is the daughter of the late George Kingsley, and niece to the authors of "Ravenshoe" and "Hypatia."

As late as March 23d the relief of Mafeking had not been effected. Probably when it comes it will come at no particular moment and with no dramatic entry following upon a pitched battle. What will happen will be that Colonel Plumer advancing from the north and the Kimberly relief column coming up from the South will threaten a union that would be fatal to the investing force, which will then disappear. It must be remembered, however, that both relieving columns can advance only slowly, as they must carry with them sufficient food and medical stores for both themselves and Mafeking, otherwise their presence would only add to the straits of the garrison. Colonel Plumer, moreover, is meeting with fierce resistance.

OUR LONDON LETTER.

(From our Special Correspondent.)

TWO DISCUSSIONS ON RHEUMATISM—SKIN AFFECTIONS IN BRIGHT'S DISEASE—MORTALITY RETURNS—ROYAL ARMY MEDICAL CORPS—DEFENCE UNION—A FAT LEGACY—PROFESSOR CAMERON—SIR WILLIAM GAIRDNER—TROPICAL EXPEDITION—COURT SURGEONS—DEATHS OF DRS. GRIGG AND CORY.

LONDON, March 23, 1900.

Two lengthy discussions on the same disease within a week may be thought to exhaust the subject. Yet I cannot say they have done so, for the subject was rheumatism. Dr. Caton introduced it to the Clinical Society of London in a paper referring chiefly to the prevention of cardiac complications, founded on some five hundred cases treated in the different ways prevailing for the last twenty years. About fifteen years ago he formulated a plan which he has followed since, and which consists in (*a*) absolute rest in bed for several weeks; (*b*) a series of flying blisters, each rather less than a florin, in the course of the first, second, third, and fourth dorsal nerves, followed by a poultice; (*c*) sodium or potassium iodide, gr. viii.-x. ter die. Sometimes small doses of mercury were given. Omitting all cases of slight transitory bruit, all of hæmic origin, and all which seemed due to a weakened or dilated ventricle, eighty-five cases with distinct signs remained. Of these fifty-four patients had a bruit on admission, probably of recent origin; twenty-four of them left with sound hearts, and twenty with valvular disease. Out of thirty-one cases in which the complications came on in hospital or had been observed just before admission by the practitioner attending, twenty-seven left with apparently sound hearts, three with valvular affection, and one remained under treatment. Dr Caton believes that there is a brief stage in endocarditis when treatment is effectual, and in adults this does not last longer than two or three weeks, though in children it is longer. Persistent rest is the most important measure, but he holds that there are more recoveries when all three are persevered in for at least six weeks. The bruit becomes softer, variable, and eventually vanishes. It is, however, advisable to avoid active exertion for a further two months.

The other discussion took place at the Chelsea Clinical Society, which has lately made efforts to come to the front. It was opened by Dr. W. Ewart in a long, didactic paper setting forth various opinions on various points, such as the prevalence, mortality, and preventability of the disease as compared with phthisis; infectivity and the arguments about that hypothesis; the various cases called rheumatic, with a classification; the liability of the several forms to cardiac complication, and the several methods of treatment in vogue, whether directed to the joints or to the heart. This *résumé*, able enough in its way, scarcely gave a clear idea of the author's own views—indeed it requires very close attention to disentangle disputed points in a paper of this kind read at a society. He concluded, however, with the remark that the main questions he submitted for discussion were how to prevent rheumatism and how to put a stop to the rheumatic heart evil.

As to the two discussions following these papers, I must, out of respect to your space, treat them together and that in the briefest way, touching only some of the points raised, for you may be sure the differences of opinion were marked.

Dr. Maclagan, as the introducer of the salicylate treatment, which has obtained such extensive vogue, naturally put in a plea for his own method. Salicin, he said, has an absolutely curative action on both joints and heart. What recovered in the one recovered in the other—the one structure which was not apt to do so being the endocardial lining. He could not, therefore, accept Dr. Ewart's statement that the heart was more often affected under salicylates than under other treatment, and asked what support could be produced for such an assertion. If salicylates controlled the rheumatic process, they must act on the heart as well as the joints. The difference is that the heart recovers more slowly because we cannot give it the absolute rest that we can to the joints.

Dr. Sansom and others expressed their confidence in the salicylates, Dr. A. E. Garrod remarking there must be something in a treatment that had been almost universal for twenty years, although he did not think its influence over the heart very marked. Dr. Hood fancied that there was more crippling after this treatment, and that we must not be led astray by its great power to relieve pain. He had collected ninety cases in which cardiac disease came on while the patients were under the influence of salicylate. He usually employed a modified alkaline treatment. Here I may say many practitioners of experience are in the habit of combining the alkaline and salicylate treatments in various ways. Others prefer the iodides, especially later on, or as soon as the salicylates have arrested the pain. Comments were also made on the comfort of the patient under the salicylates, though it was asserted that these had also disagreeable and sometimes dangerous effects.

Now, as to blistering. The plan is older than any of the speakers seem to remember. No one referred to Cotugno, and only one to the late Dr. Herbert Davies, who published in the "London Hospital Reports" for 1864 a series of twenty-four cases treated exclusively by blistering, and all of these left the hospital without any cardiac imperfection. I remember very well Dr. Davies and this treatment of acute rheumatism. With much swelling, he put a small blister near to the joint, and his success was great, both as to pain and fever.

Sir D. Powell suggested that in young or nervous patients blistering might somewhat interfere with the absolute physiological rest that was of the greatest moment. This, however, has not been the experience of those who have tried it.

Dr. Sansom professed to have seen the treatment by blisters, both big and little, and thought they only added to the patient's discomfort. Dr. Longhurst would not blister nervous women or children, nor would he confine himself to any one plan of treatment. Dr. Seymour Taylor said a blister gave the greatest relief to a rheumatic joint. If applied for the heart, it should be over the upper dorsal segments of the cord. Dr. A. Morison found a blister over the heart quieted it to a marked extent, and he mentioned that the late Dr. Hope advocated blisters some sixty years ago.

The question whether the blister should be opened was mentioned. If it acted by removing the poison, one would consider that the fluid should be evacuated, but one speaker said no, as the serum would be antitoxin, which is certainly carrying the serum notion far. Effusion into the joints is generally accompanied by relief to the general symptoms, and it is natural to attribute this to the withdrawal of the poison. If this is so, blistering would be a reasonable attempt to withdraw it from the system. That the toxin should then change to antitoxin is a mere assumption.

At the last meeting of the Medico-Chirurgical Society Dr. Hugh Thursfield read a paper on "The Skin Affections Met with in Bright's Disease," and so gave the dermatologists a chance of which they were slow to avail themselves. Dr. Crocker indeed made some remarks, but admitted his experience did not show whether an eruption necessarily suggested renal origin. Considering the relations of the skin to the kidney, one might anticipate a more frequent complication than is actually found. But unless the skin affection is very troublesome, it would be neglected in the presence of so grave a disease as Bright's. Dr. Thursfield proposed to classify the affections thus: (*a*) Those in the early stages, as pruritus, eczema, and urticaria; (*b*) those in the final stages, as erythematous, bullous, and desquamative eruptions; (*c*) purpura and hemorrhagic cases; (*d*) those seen with marked œdema, and he thought due to local infection by pyogenic microbes. There was some conversation on the supposed influence on prognosis and other points, but it did not appear that the speakers had any exact information to give.

The mortality returns show further improvement. In the large towns the rate has fallen to 20.3. London's register of deaths last week was 1,659, which is 315 below the average for the corresponding week.

Lord Methuen, in an official dispatch, brings to the notice of the authorities Major O'Donnell and Lieutenant Delass, of the Royal Army Medical Corps, for their "indefatigably attending the wounded under fire." The last named, he says, advanced in the open and attended Captain Gordon, and afterward Major Robinson and others, "under a fearful fire." Other reports of this kind are adding to the fame of the Royal Army Medical Corps. The gallantry and devotion of the corps has also been acknowledged by the government in the House of Commons, and that in a manner which should warn the War Office that its treatment of the medical service will be one of the counts in the indictment to be tried after the war.

The Medical Defence Union held its annual meeting last week. There was some talk about amalgamation, but it was stated that the Council had decided against the proposal. It seems a pity that division should weaken the two societies.

The late Prof. David Edward Hughes, F.R.S., has left a sum of between three and four hundred thousand pounds to the London, Middlesex, Charing Cross, and Kings College hospitals. The capital is to be kept under certain conditions.

Dr. Hector Cameron succeeds Prof. George Buchanan in the chair of clinical surgery the latter has resigned in Glasgow University. I also hear that Sir William Gardiner is resigning the professorship of medicine in the same university. This veteran clinical teacher finds with advancing years that it is a strain on his eyesight to keep up with bacteriological and microscopical work.

A second malarial expedition is organized by the Liverpool Tropical School.

Lord Lister succeeds the late Sir James Paget as sergeant-surgeon to the Queen, and Mr. Treves is appointed one of Her Majesty's surgeons extraordinary.

The death is announced in his sixty-first year of Dr. W. C. Grigg, late physician to Queen Charlotte's Hospital, and a past president of the Gynæcological Society. He recently retired from active practice. He went to South Africa, thinking he might be of some use, but contracted typhoid at the Modder and died in Wynberg Hospital on the twelfth inst. He was an Edinburgh graduate, a genial gentleman, and long enjoyed a good position among the obstetrical men of London.

Another death I must note is that of the director of the Animal Vaccine Establishment, Dr. Robert Cory, which took place on Monday. He was a Cambridge graduate, a F.R.C.P., and physician in charge of vaccination at St. Thomas' Hospital.

EARLY OPERATIONS FOR CANCER.

To the Editor of the Medical Record.

Sir: The discussion on cancer before the New York Academy of Medicine cannot have failed to interest a large number of your readers.

Leaving out cancer of the respiratory and digestive tracts, because cancer in these locations does not often come under my observation, I will refer only to malignant disease of the uterus and female breast. In the paper on cancer of the breast, by Dr. Abbe, and cancer of the uterus, by Dr. Coe, early and complete removal of the diseased organ was advised; and in the case of the breast removal of a large area of skin together with fat, glands, and pectoral muscles was insisted upon. This is as it should be, for anything short of this would probably not confer immunity from recurrence. The difficulty in the way of a complete cure from operation in cancer of the breast and uterus lies in the carelessness of the laity, and to a great extent of the profession, in regard to this subject. When a patient over thirty-five years of age consults a physician in regard to a small tumor of the breast, which she may have noticed some weeks or months previously, the doctor, after a very cursory examination, is apt to say, "Yes, madam, you have a lump there, but I hope that it is nothing serious; paint it with iodine or rub it with camphorated oil, and let me see you again after a while." "After a while" not being a very definite period, the patient returns any time between six months and a year later; she then has a tumor the size of a hen's egg. The nipple is retracted, the axillary glands are enlarged, and the patient suffers from lancinating pains in the breast and sometimes in the arm of the affected side—in fact, when any old woman could make a diagnosis. The case is now referred to a surgeon, who does as radical an operation as can be done under the circumstances; but the disease recurs in a few months and the patient dies a short time later. The practitioner who first saw the case lays the flattering unction to his soul that he has done his duty by his patient—he has not been rash, but conservative. Could the grave speak, how eloquent and damning an accusation could be brought against this sort of conservatism, which ought rather to be called criminal procrastination!

In cases of cancer of the uterus the same carelessness is met with. A woman about forty years old begins to have irregular discharges of blood from the vagina. She consults some elderly dame, who says, "It's all right, dear. I had that myself when I was getting change of life." It may be that she consults the family physician, who indorses the opinion of the old lady to the effect that the irregular bleeding is due to the advent of the menopause. He prescribes ergot or hydrastis or some equally useless stuff, and sends the patient away satisfied that all will be right in time. Delusive hope! The bleeding continues; leucorrhœa and an offensive watery vaginal discharge supervene, and at this stage the patient is advised to consult a gynæcologist, who finds that the disease has passed the operable stage. Had the physician who was first consulted made a careful vaginal examination, it is probable that the true nature of the disease would have been detected; and if the patient had been promptly referred to an operative gynæcologist, and a vaginal hysterectomy performed, the chances of a radical cure would have been very good.

Vaginal hysterectomy for cancer of the uterus in the early stage gives excellent results, but if the disease has invaded the vaginal walls and broad ligaments, even though the operator may be able to extirpate the uterus, no benefit results from the operation, as the disease always recurs and rapidly goes on to a fatal termination. It is highly desirable that the laity and a large proportion of the members of the medical profession should realize that the so-called change of life is a physiological process, and quite as natural as the coming on of the menstrual periods in a young girl, providing the generative organs of the woman are in a normal condition; and that unusual symptoms connected with the pelvic organs occurring at that time of life are probably dependent upon some pathological condition which demands recognition and proper treatment. Viewed in this light the menopause as such will cease to be a bugbear to womankind in general—a period in her existence during which all sorts of terrible occurrences are supposed to be entirely *en règle*—and when symptoms indicative of disease of the genital tract show themselves she would appreciate their importance and apply for treatment before it is too late. Viewed in this light by the medical practitioner the menopause will cease to be for him a stumbling-block and a rock of offence.

G. H. Balleray, M.D.

New York, March 24, 1900.

Circumcision.—Inject one drachm of a five-per-cent. solution of eucaine beneath the prepuce and retain it there. With a three-per-cent. decinormal saline solution of eucaine inject just beneath the skin about two minims at each puncture, each new puncture being at the margin of the preceding bleb, until the line to be incised is anæsthetic. Now let out the solution held beneath the foreskin and proceed with the operation, using carbolic or chinosol solution and not bichloride. —Gerald Dalton.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, March 20, 1900.

John Huddleston, M.D., Chairman.

Treatment of Rheumatism at the New York Hospital.—Dr. Hughes Dayton read a paper on this subject (see page 585).

Treatment of Rheumatism at Mount Sinai Hospital.—Dr. L. A. S. Bodine read this paper. He said that in acute articular rheumatism, after a thorough clearing out of the alimentary canal by means of calomel and salines, sodium salicylate was used, in doses of gr. x.–xv. every three hours. Sodium bicarbonate was often associated with it in order to maintain a proper alkalinity of the urine. In addition, rest in bed and fluid diet were insisted upon. If, for any reason, the salicylates were not well borne, owing to tinnitus aurium, eruptions, or gastric disturbances, either oil of wintergreen or the citrate or acetate of potassium was used as a substitute. The bowels were kept open by cathartics, preferably by the use of salines and by enemata. Phenacetin, acetanilid, antipyrin, and codeine were all used to relieve pain, and sometimes, though rarely, morphine. To produce sleep, trional, in combination with sodium bromide, was a favorite remedy. During the acute stage only a fluid diet was permitted. Nitrogenous food was avoided as much as possible, and large quantities of water were taken by the patients daily. The salicylates were always given well diluted, and never on an empty stomach if this could be avoided. Methyl salicylate was used locally. Tincture of iodine, bandaging, ice-bags, and elevation of the limb were measures in use for inhibiting the exudation. If in spite of these the effusion continued to increase, the joint was aspirated to determine the nature of the contents of the joint cavity. Hot-air baths at a temperature between 200° and 400° F. had been used locally for from twenty to thirty minutes daily. During the convalescent stage iron, strychnine, and quinine were administered. The salicylate of iron was often employed. After the temperature had remained at the normal for two or three days, the diet was enlarged to consist of eggs, bread, potato, toast, and fresh vegetables, but meats were still excluded. All patients were kept in bed for three or four days after the temperature had reached the normal point.

Differential Diagnosis of Chronic Rheumatism.—Dr. James J. Walsh read this paper. He said that there were four classes of cases, viz., (1) recurring subacute rheumatism, the attacks occurring at short intervals and yielding rather promptly to the ordinary treatment for rheumatism; (2) cases presenting symptoms of articular rheumatism, and recurring again and again in children, especially during damp weather, or alternating with chorea, tonsillitis, or certain cutaneous manifestations; (3) cases in which the joint lesions occurring during an acute attack persisted and became worse, sometimes permanently injuring and deforming the joint—true chronic rheumatism; (4) a numerous class of cases often diagnosticated as chronic rheumatism, but really consisting of a varied assortment of ailments. The latter were specially characterized by pain, and this pain was often relieved by the treatment usually employed for rheumatism. The reason was that this medication usually consisted in the administration of the coal-tar products, which relieved pain not only of rheumatism, but pain in the peripheral nerves produced by a great variety of causes. Any one who knew how soothing were the salicylates when used in surgical dressings could readily understand this. A similar method of treatment had proved exceptionally useful in relieving the pain associated with the formation of an abscess at the root of a tooth. A very common affection often diagnosticated as rheumatism was weak foot, or flat foot, and it was frequently difficult to convince such patients that the cause was not rheumatism. If, however, a small pad of felt was placed under the inner border of the sole of the weak foot, it would not be difficult to convince one's self of the correctness of the diagnosis. A somewhat similar condition was found among dentists from the frequent use of the dental engine. In these instances the pain was not felt in the foot used to operate the engine, but in the other foot which sustains the weight of the body at that time. There were, of course, many other occupation neuroses which were apt to be confounded with rheumatism. These should be excluded before diagnosing chronic rheumatism. Many of these functional cases were observed in persons who had become anæmic, or whose general health had become temporarily deteriorated. He had recently known of two cases of varicose veins of the leg of slight degree that had been treated for rheumatism because of the pain that had been felt in the vicinity of the knee.

The Hot-Air Treatment of Chronic Rheumatism.—DR. THOMAS E. SATTERTHWAITE spoke of this method of treatment. He said that it was an old one, but until quite recently had been carried out only under certain difficulties. The great objection to the older bath method of giving it was the breathing in by the patient of the superheated or moist air, and to obviate that the well-known "hot box" had been devised. In this the body, excepting the head, was exposed to the heat. In the modern machines, such as those exhibited by him now, the temperature could be readily raised to 400° F. The essential idea was to keep the body dry while the air about it was superheated. The hot air was not allowed to impinge directly upon the skin, because unless provision was made for the absorption of the perspiration the skin would be scalded. By wrapping the limb in Turkish towelling this was accomplished. Again, the inner surface of the cylinder was lined with asbestos to avoid contact of the skin with the heated metal. These forms of apparatus had been used since May 30, 1893. The speaker said that the claim put forward for such apparatus by those competent to judge was that the superheated air was merely an adjuvant to other treatment. Dr. George L. Kessler, of Brooklyn, after an extensive experience with the method, had drawn the following conclusions as to the effect of the treatment: (1) It produced contraction followed by dilatation of the superficial blood-vessels; (2) the pulse became more rapid, but at the same time its strength was improved; (3) the bodily temperature rose from one to six degrees, and the accompanying perspiration was profuse and acid; (4) the respirations were also increased; (5) nerve exhaustion was experienced if the treatment was too prolonged. The limb should be snugly swathed with about four thicknesses of blanketing or Turkish towelling. If this was not snugly applied, the perspiration might lodge between the towelling and the skin and cause blistering of the skin.

Brief Notes on Rheumatic Joints Treated with Hot Air.—DR. H. W. GIBNEY gave, in this paper, extracts from the clinical records of several cases which he had successfully treated with the portable hot-air apparatus. He said that in several cases of rheumatic flat foot he had been able to break up the adhesions more satisfactorily by first exposing the part to the hot air.

Use of Electricity in Chronic Rheumatism.—DR. W. J. MORTON read a paper on this subject, dealing chiefly with the effect of the high potential high-frequency current. He used the current in one of its forms in the treatment of chronic rheumatism. The current was obtained from a powerful influence machine, using a condenser. One form of this current, but little known as yet, was that designated as "the electric-wave current." The patient, in this instance, was subjected to what might be called a "condenser current." With long sparks passing the patient becomes practically one coating of a Leyden jar, and was subjected to very powerful condenser waves. Under the use of this current, heat production was increased, and while the body weight was diminished during these applications, it was restored to its former amount in the interval. The therapeutic effect of the increased nutritional activity of the patient's organism was an improvement in the general health and nutrition. These currents could be applied locally as well as generally. Most chronic diseases were constitutional, and many forms of chronic arthritis might be so considered. Certainly, in most cases of rheumatism the physician aimed to treat the diathesis as well as the local manifestations. The electrodes might be of any pliable material, block tin being specially suitable. The spinal electrode used by him measured one inch by twelve inches. When a strictly local effect was desired, a small electrode was selected. These block-tin electrodes were wrapped about the joint without any moistening or covering. Instead of block tin, he often made use of metallic cloth, such as was furnished by military clothing stores. From this cloth rude garments could be quickly made and applied. All cases received an application of the wave current for a period varying from fifteen to thirty minutes. If the patient felt exhausted after the treatment, it was evidence that the application had been too prolonged. The application of the sparks would, in a single treatment, temporarily relieve the pain and increase the mobility of the affected part. In subacute and chronic rheumatism the treatment was general, after the manner described, and this was followed by a local treatment with the sparks if these could be borne. He had tried the hot-air treatment and many other methods, but had found none of them equal to the electrical treatment just described. It was particularly applicable to gout, and when there was only a watery œdema present the relief was apt to be permanent. The speaker said that the progress of rheumatoid arthritis could be arrested in any stage of the disease. If seen in the early stages, it could be arrested easily and quickly; if it was already more advanced, such a result would be secured only after more prolonged treatment. The long spark applied to each individual joint affected seemed to him essential in establishing a new and improved joint nutrition. One of the first effects noticed was that the shiny appearance of the skin disappeared. In private practice he placed all his rheumatic patients on a meat diet.

DR. WILLIAM M. LESZYNSKY commented upon the fact that a large number of patients complaining merely of pain were not examined, by many physicians, but were treated for rheumatism or neuralgia. Nothing had been said that evening regarding a simple method of local treatment—the wet pack. He thought much could be accomplished in many cases by means of the wet pack, assisted by massage and passive motion. A recent case was recalled in which there had been much swelling, stiffness, and pain in the hand following an attack of acute rheumatism. In this case complete recovery had taken place at the end of three weeks simply from the use of the wet pack at night, and the local application of oil of wintergreen and massage during the day. This was no unusual experience with him. He had not personally had a satisfactory experience with the use of static electricity in the treatment of chronic articular rheumatism, although he had, like many others, obtained most brilliant results from such electrical applications in cases of muscular rheumatism. In private practice he had not been willing to confine himself to the use of static electricity. A common fault was, not to apply this current long enough, and hence the frequent assertion that this treatment succeeded chiefly by its mental effect.

The Splint Treatment.—DR. MORRIS MANGES said if one were dependent solely upon the use of the salicylates convalescence would be slow and unsatisfactory, and there would be many complications. It would not be too emphatically stated, to say that we were far from having any specific treatment for rheumatism. To treat rheumatism by the salicylates alone was certainly an error. The physicians at the Mount Sinai Hospital had been particularly impressed with the intense anæmia observed in their cases of rheumatism. Another fact which had impressed them there was the value of splinting the affected joints. These joints should be absolutely immobilized, leaving, if desired, an opening for local medication. Any one who had not tried this method would be agreeably surprised at the result. It was exceedingly important also to watch the urine, for this alone afforded a proper index to the quantity of alkali to be given. The urine should be made alkaline, and kept alkaline. If a pronounced alkaline treatment was combined with a moderate salicylate treatment, and proper attention was given to the immobilization of the affected joints, and to the care of the heart, the results would be good. The hot-air apparatus was useful, but should not be relied upon too much. There were certain drawbacks to the use of this apparatus, one of these being danger of fire. He knew of one or two instances in which a subacute rheumatism had been rendered acute again by the chilling which had followed the exposure of the part to the cooler atmosphere of the treatment room after having been removed from the hot-air chamber.

DR. MARY PUTNAM JACOBI said, with regard to the question of differential diagnosis, that no mention had been made of the tendency to confound incipient rheumatoid arthritis with gouty deposits around the joints. She had recently had an opportunity of witnessing the good results obtained by Dr. W. B. Snow in rheumatoid arthritis from the use of the electric-wave current. There could be no doubt about the excellent effect of electricity in muscular rheumatism.

Lactic Acid a Useful Remedy.—DR. G. L. KESSLER said that he had treated about three hundred and fifty cases of rheumatism with the Sprague hot-air apparatus. In the chronic form of rheumatoid arthritis he had found the deformity lessened and the mobility increased. Out of twenty such cases, eighteen had been positively benefited, and five of the patients had resumed work, although unable to work for several years previously. In the cases in which the joints suddenly became stiff good results were obtained from the use of hot air locally, and the free use internally of lactic acid. He did not pretend to say how this remedy acted, but was positive of the good effect. The treatment should be continued for a number of months. He would not think of treating a case of acute articular rheumatism without the aid of the salicylates, because he looked upon rheumatism as an acute infectious disease. He would never think of immobilizing a rheumatic joint, because he met with so many such joints which had become stiffened, and which proved most obstinate to subsequent treatment. He did not think it safe to run the temperature in the hot-air apparatus above 350° F. In such apparatus the temperature was indicated by a thermometer affixed to the top, but there the temperature was at least 20° lower than in the lower part of the hot-air chamber. Burns should not occur if the temperature did not exceed 350° F. For the local application of heat in cases of gout, the Japanese hand-warmer would be found exceedingly convenient. Certain cases of neuralgia seemed to relapse after the hot-air treatment, apparently from the subsequent chilling of the part.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, March 22, 1900.

J. RIDDLE GOFFE, CHAIRMAN.

New Operation for Repair of a Complete Laceration of the Perineum.—DR. J. RIDDLE GOFFE expected to present a patient showing the results of a new operation which was suggested by Dr. Kelly at the meeting of the American Gynæcological Society, which met in Philadelphia last year. It was suggested for those cases in which the tear went through the sphincter muscle, and up to the rectal wall. Instead of splitting the tissues and dissecting off the mucous membrane of the vagina, one should commence above and work down, so forming an apron, which turned down and covered the anus, and which was held in position by an artery clamp. Using a figure-of-eight suture, the fascia of the sphincter muscle was taken up and ligated; this drew together the fascia and brought up the sphincter muscle until it got in the middle line. Dr. Ristine, of Knoxville, Tenn., had been using this same procedure during the past two years, and Dr. Kelly acknowledged his prior claim. In this operation nothing must be done within the rectum whatever, and so dangers from infection were lessened.

DR. EDWIN B. CRAGIN said the advantage of this new operation was that the rectum was left intact, and the only objection was that there was a flap which was liable to superficial sloughing. He thought the operation would come into general use.

DR. GEORGE G. WARD had operated last summer on three cases in which he did not use this new method, and all did well. He was careful not to tie the sutures on the rectal side. The torn roof of the rectum was picked up but not penetrated. The ends of the sphincter muscle were dissected out, and, with traction, silver wire sutures were passed, and these were reinforced by catgut. In none of these cases did a fistula result.

DR. SIMON MARX thought that another objection to this operation was that the line of union between the mucous membrane was such a small one that possibly sloughing of that part might occur. In a case he had operated upon that day he found that he did not have enough vaginal tissue to make an anterior rectal wall. He feared sloughing of the tissue.

DR. BALLERAY said he was not disposed to try this new operation just yet, because, up to the present time, he had had but one failure. In the earlier days he had practised the method of Emmet, regarding which operation he once heard Dr. Price say that it was a wonder that the patients did not die of tetanus; but he got excellent results. In lacerations not involving the sphincter he did the Pozzi method.

Results of Conservative Treatment.—DR. GEORGE G. WARD had operated upon a case recently which was interesting because two years ago the patient had had a laparotomy performed for ovarian disease, and the left tube and ovary had been removed, the right ovary being left *in situ*. Last Saturday he operated because there was an ovarian cyst upon the right side the size of a small orange. When the abdomen was open, he found great difficulty in freeing the cyst on account of the extensive adhesions. The bowels were adherent in three distinct loops to the side of the uterus, and it was difficult to tell which was cyst and which was bowel. In one of these cases the bowel was torn through and in the other two there was denudation of the peritoneal covering. The point of interest was as to the conservative work done upon the ovary; it was a question how far we could go in conservative work. Was an ovary treated conservatively apt to undergo cystic degeneration?

An Enormous Corpus Luteum.—Dr. Harris, of Paterson, N. J., described an interesting case which showed the importance of conservatism. A trained nurse, aged thirty-three years, from whom a large cyst and the left ovary had been removed when she was twenty years old, presented herself to him about four months ago for a slight hernia occurring in the abdominal incision. When he opened the abdominal cavity, he thought he would investigate the condition of the right ovary on account of the pain that she complained of. He did so, and found a condition that he then did not understand. The ovary was about the normal size, with a reddish-brown colored mass overtopping it. With a scalpel there was no difficulty in shelling out about two-fifths of the ovary. This overtopping mass was about one and one-eighth of an inch long, and occupied about two-fifths the entire length of the organ, and was of an entirely different color. This mass was removed and sent to the bacteriologist at Johns Hopkins Hospital, Baltimore, who pronounced it a corpus luteum.

Dr. Edwin B. Cragin thought that each case should be decided on its merits. If the patient was young, and expected to be married, she should be given the benefit of the doubt, and the ovary should be left; but if the patient was an elderly woman, and had given birth to a number of children, and if one suspected the ovary to be diseased, it should be taken out.

Submucous Fibroids.—Dr. Simon Marx showed these specimens, two in number, and referred to the difficulty of the diagnosis in one case and the ease of diagnosis in the other; again, both operations were done with the greatest facility, yet one patient made an uninterrupted recovery, while the other died three hours after operation. In the case that offered difficulty in diagnosis, the patient was rather an ignorant woman, who had been married eight years. She was well up to two years ago, when there was discovered a small tumor in the pelvis; otherwise she was perfectly well. Until six months ago she menstruated every four weeks, the discharge lasting five days, and not being excessive. During the past three months she had menstruated scantily. Examination showed a tumor with a soft, boggy feel, reaching as high as the umbilicus. The doctor first thought of pregnancy. Examination for the fœtal heart did not reveal any. Hegar's sign was not present. Intermittent uterine contractions were not present. Abdominal section was advised because of the pressure symptoms, the dyspnœa, and the symptoms referred to the bladder and rectum. The abdomen was opened, and he then thought he had to deal with a pregnant uterus, but the history of the case prompted him to go on and do a total extirpation; he knew the tumor had been discovered six months ago and had been growing since, but he could not hear the fœtal heart, no fœtal life was indicated, and Hegar's sign was not present. The tumor proved to be a large submucous fibroid. The other case referred to was that of a woman who died three hours after the operation, probably from shock. She had atheromatous blood-vessels, which no doubt were a factor in its production.

Two Cases of Appendicitis.—The next specimen shown by Dr. Marx had been removed from a young girl about twenty-two years of age, who had had repeated attacks of appendicitis; she desired operation because she was going abroad and wished to be cured here. The McBurney operation of splitting the muscle fibres was done, and she made a good convalescence. Another specimen had been removed from a single woman aged thirty years. She had had one mild attack of appendicitis three years ago. She complained of intense headache, and almost constant vomiting every morning. She was repeatedly examined, but no diagnosis was made. Her eyes, nose, and all parts were treated without benefit. A rise of temperature gave severe headache. McBurney's operation was done, and the tip of the appendix was found bent upon itself and adherent at the base, where it sprang from the cæcal wall. She made a good recovery.

Appendicitis; Operation, Infection, Death.—This patient, Dr. Marx reported, had had a baby two or three years ago. She had considerable trouble on the right side, which was thought to be due to movable kidney. The kidney was stitched in place, but the pains continued. She developed quite evident symptoms of recurring appendicitis. Because she had an adherent and retroverted uterus an operation was decided upon and done, the appendix being taken out; it was quite long and full of pus. The left ovary was liberated from adhesions and the uterus sewed in place. The convalescence was an ideal one, the pulse seldom being over 80. On the day she was to be discharged, when the speaker went to bid her good-by, he found the pulse 100, and the temperature 100° F. That night the temperature was 103° F., and there was pain in the abdomen. A boggy mass was found posterior to the uterus. A posterior section was made through the vagina, and stinking pus was discharged; the finger on being introduced passed up into the cæcum. A rapid acute peritonitis developed, and the patient died with absolutely a normal temperature, but an enormously rapid pulse. The speaker asked: Why had she a normal convalescence, and why, at the end of the fifteenth day, did she have these symptoms, and within twenty-four hours develop an enormous boggy mass? He did not know, unless it was from a late catgut infection. Catgut infection, sloughing of the appendix stump, and the development of a sero-purulent abscess, were the conditions that probably followed.

Dr. Balleray related an instance of a woman aged thirty-five years who had recurring attacks of pain. Examination showed a short pedicle, partially twisted, and he wondered whether the pedicle did not twist itself, giving the patient pain, and then untwist itself.

Cases of Ectopic Gestation.—Dr. Balleray showed this specimen. The patient was unmarried but was leading a dissolute life. She entered the hospital with an acute gonorrhœa. She had skipped over her period six weeks, when she was taken with severe pain. There were two small masses posterior to the uterus, the mass on the right side becoming larger when pain was present. The abdomen was opened, and the mass on the right side was found to be a blood cyst, which accounted for the sudden increase in size when pain was present. On one side there was a pus tube. The entire pelvis was swabbed out, and the patient put to bed with the pelvis elevated. After the operation the temperature never rose above 100° F. It was interesting to note that there was an absence of drainage when drainage seemed to be indicated. In this instance there was a ruptured ectopic gestation, with a pus tube and a cystic ovary on the opposite side. In another case, also shown by Dr. Balleray, an ovary and a tube had been removed from a woman twenty-five years of age, who had been married three years. She had never borne children, but had suffered all her married life. Soon after marriage she had had menorrhagia, very profuse, and later metrorrhagia. She had a pyosalpinx. When she was operated upon, no blood was found in the peritoneal cavity. The tube was adherent to the rectum. On the other side was a small mass which was thought to be an ovarian cyst but proved to be a small cyst in the broad ligament. There had been a ruptured ectopic pregnancy in the early stage, in which the fœtus and a small amount of blood had escaped into a circumscribed space in the pelvis, which was made by adhesions formed by a chronic disease of the ovary and tube.

Some Points in the Management of Obstetric Cases in Private Practice.—Dr. J. B. Cooke read this paper. He emphasized the importance of physicians making more careful and accurate histories of all their cases. He advised the use of certain cards which could be carried in the pocket; one card related to the history of the pregnancy, the second to the labor, and the third to the puerperium. These cards were very complete, and, when used, should be placed on file for future reference. The importance of an examination of the urine was entered into, and, on account of patients neglecting so often to comply with requests to furnish urine, he advised the use of labelled bottles, which were to be sent to the physician's office on certain days at a certain time. Such a procedure impressed the patients, and one could get the desired urine. He emphasized the point of maintaining absolute asepsis from the beginning of labor to the end, and told how he attained it. Boxes containing sterilized water, certain solutions, gauze, etc., he had packed at his office and ready for transportation. When summoned to a case the Manhattan Delivery Company called for and carried one of these boxes to the patient's home.

Dr. Simon Marx thought that accoucheurs had trouble enough in carting instruments and dressings, without being obliged to carry sterilized water. He said he was a nihilist so far as the uterine douche was concerned. It was supposed that the woman was healthy; that the living baby, or a baby that died within a few hours, was also aseptic; that the hand of the accoucheur was also aseptic; therefore he seldom used the douche before or after labor unless there was a bad discharge or a putrefied child. He was also a nihilist in regard to urinary analysis. He examined the urine of a pregnant woman once in every two weeks; he seldom examined for albumin, but always for urea. He believed that more women died from the toxæmia of pregnancy than from the true acute nephritis of pregnancy. He had seen women die when there was not a trace of albumin, and others get well when the urine was filled with albumin. If the amount of urea was diminished, he believed something was wrong with the patient. If a woman had a large amount of albumin in the urine, only one kidney might be affected, and the woman should be allowed to go to term. He did not believe so much in pelvimetry. Personally he had found small pelves and small children in many instances, and no trouble was experienced in handling these cases. On the other hand there was the greatest source of danger to women from a form of contracted pelvis in which there was minor contraction but a very large child. He knew of three cases, in two of which preparations were made for doing a Cæsarean section, and, too, by a distinguished operator; the labor progressed without interference, and he was later called in to sew up a tear. In another case a symphyseotomy was thought to be indicated; in this instance the position, which was a mento-posterior at the brim, was not taken into consideration; the correction of this was soon followed by delivery. His method of procedure was as follows: From the seventh month, if he found a relatively normal pelvis, he attempted the engagement of the head by Hofmeier's method; if the head would not engage he induced labor. Many of these heads would accommodate themselves and readily engage by the suprapubic method.

Dr. Balleray advocated the douche before and after labor. He had seen a case of puerperal sepsis following a normal labor; if the douche had been used before labor puerperal sepsis would never occur. He used a solution of creolin and green soap as a preliminary douche, which was followed by a solution of bichloride of mercury, 1 : 5,000, and then by sterilized water. After labor he used the douche as long as the patient remained in bed, giving it twice daily. He agreed with Dr. Marx that pelvimetry gave many misleading indications. He had known cases in which there was supposed to be a contracted pelvis, and a Cæsarean section was performed; subsequently the woman gave birth to a child in the natural way by natural efforts, and the child was as large as its predecessor. He knew of another instance in which symphyseotomy was done; here, again, subsequently a child of about the same size was born naturally.

Dr. Edwin B. Cragin thought the great advantage to be derived from Dr. Cooke's paper was in emphasizing the importance of details in the care of the women before and after pregnancy. Regarding the examination of the urine he could hardly agree with Dr. Marx. He believed both albumin and urea should be tested for; either one might be present as a danger signal. These occurred in some cases as premonitory symptoms, and should be looked out for. Regarding pelvimetry all physicians acknowledged that they were much disappointed with it. At the Sloane Maternity, pelvimetry showed sometimes that they had to deal with a small pelvis, yet the child came through all right. Pelvimetric instruments were only an additional help in determining the relationship between the head and the pelvis. In regard to douches, when he went on duty at the Sloane Maternity Hospital it was customary to use the douche before and after labor; he allowed them to continue the practice for a number of months. He then thought he would try to do without douching. In looking over the temperature charts he found there was just a little increase in temperature during those months, so he ordered the douching to be resumed. A few months later the temperatures, as a whole, went higher than they did when no douches were used, so the douches were stopped altogether, and had not been used for several months, unless special indications were present. The parts might be disinfected when soap, bichloride, ether, etc., were used, but he did not believe the douche could do it. He wished to emphasize the importance of instructing the nurse to take the baby's temperature as well as the mother's, during the first week. This starvation temperature showed whether the mother was furnishing her child with proper nutriment.

Dr. Marx asked Dr. Cragin if it was the urea or the albumin that killed in these cases.

Dr. Cragin replied that either acted as the "red flag."

Dr. Marx said it was the urea that killed; even if the urine was loaded with albumin, it was the urea that killed.

Dr. Cragin stated that one year ago he tried the expectant plan with albuminurics, and he found the mortality was higher, and he regarded this as one of the reasons why women thus affected had better not go on with pregnancy. He agreed with Dr. Marx that the examination for urea was very important, and in fifty or fifty-five per cent. of the cases in which it was present he found that the urea did not subside under rest in bed, flushing the alimentary tract, hot baths, and stimulating all the emunctories, and that it was better to remove the pressure by inducing labor. He did not believe that all was known about this toxæmia.

Plastic Operations on the bladder are often useless, since the bladder has diminished resisting and expulsive power, and incrustations are apt to form.—Sonnenburg.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 19, 1900.

FREDERICK HOLME WIGGIN, M.D., PRESIDENT.

Report of a Successful Case of Excision of the Cæcum with End-to-End Anastomosis.—DR. FREDERICK HOLME WIGGIN reported a case of this kind in which there had been long-standing and continued recurrences of appendicitis, which had led to complete occlusion of the bowel. The patient, a woman of fifty-four years, had been seen by him in consultation with Dr. D. R. Rodger, of Woodbury, Conn. She gave a history of recurring attacks of appendicitis extending over a period of ten years. Her last attack had been exceptionally severe, and had begun about six weeks previously. She was emaciated and mentally depressed, and examination showed that her gums and tongue were swollen and red, and that there were ecchymotic spots all over her body. Her pulse was 74 and her temperature 99.4° F. Bimanual palpation revealed a tumor attached to the uterus and broad ligament, and extending up into the right inguinal region. An incision was made over the right rectus muscle, and the tumor exposed. It proved to be within the cæcum and appendix. Fearing that malignant disease was present, the bowel had been divided on either side, some distance from the tumor. The mesenteric attachment was clamped off before the vessels were divided, and then the vessels were caught with forceps and ligated, so that it was estimated that the patient had not lost over an ounce and a half of blood during the whole operation. In making the anastomosis the suture method of Maunsell with some modifications was followed. Large quantities of foul fecal matter had been discharged from the bowel during convalescence, showing that it must have been retained in the intestine a long time. Convalescence was satisfactory, but was rendered somewhat tedious by the presence of a condition analogous to scurvy. The condition of the tongue and gums at the time of operation, and the occurrence of a bloody vaginal discharge shortly afterward, served to emphasize the nature of this constitutional vice. Convalescence was greatly assisted by the early and constant use of saline enemata and by the early administration of food in considerable quantity. Dr. E. K. Dunham had examined the specimen, and had found evidence of nothing more than a chronic inflammatory growth.

Symposium on Serum Therapy.—DR. E. K. DUNHAM introduced the general subject by a brief paper. He said that the practice of serum therapy was based on the fact that animals or man could acquire immunity against a given infection. The blood and the lymph of the body were known to confer immunity in some instances, especially when freshly drawn, and it was probable that this action was dependent upon the presence of certain enzymes or ferments, which had a solvent effect on the bacterial cell and its envelope. It was probable that this action was closely related to the agglutination familiarly exemplified in the Widal reaction for typhoid fever. The most philosophic theory of immunity was one based upon the chemical theory of the action of poisons. It was known as Ehrlich's "side-chain hypothesis." The protein molecule was known to be one of very great complexity. The chemist expressed the constitution of such complex molecules by means of a nucleus, consisting of closely united atoms, and added to these other atomic combinations or radicles composed of atoms more loosely attached. These were known as "side-chains." The molecule might suffer cleavage, splitting into simpler combinations, and the direction of such cleavage would depend upon the conditions under which the splitting took place. Under ordinary circumstances the tissues of the body possessed a certain reserve of activity. When this was drawn upon, it was not merely replaced, but an additional store was laid by. Ehrlich supposed that such an excess of side-chain radicles might be stored up and appear in the circulation as an antitoxin.

Natural Immunity.—An animal might be naturally immune to substances poisonous to other animals. Thus, rabbits were not affected by atropine; fowls were not susceptible to the toxins produced by the tetanus bacillus. According to Ehrlich's theory, natural immunity would be the necessary result of the absence of side-chains having an affinity for a particular poison, and the blood of naturally immune animals would not contain any antitoxin because the conditions for its production were not present.

Active Immunity.—Active immunity was that which resulted when gradually increasing amounts of poison were introduced into the organism, whether in solution or formed in the body by the growth of bacteria. It was not essential for the growth of active immunity that toxic symptoms should be produced. An excessive dose of toxins, according to the theory of Ehrlich, arrested the function of the cells, but in smaller dosage it caused the formation of an additional store of side-chains. The theory also showed that the antitoxin introduced must bear a definite chemical relation to the poison which had called forth its production. It did not follow that all of the cells of the body were equally affected; the toxins might be localized. When this localization obtained, the particular side-chains having an affinity for the toxins must be confined to the tissues susceptible to the poison. In the case of tetanus, they should be found in the nervous system, but those tissues should be able to neutralize to some extent the toxins. Experiments with tetanus had shown this to be the case, particularly with animals that were remarkably susceptible to the tetanus toxin. The side-chains affected by diphtheria antitoxin were probably situated in the lymphadenoid tissues, the bone marrow, the spleen, and the lymph nodes. If the animal had been partially immunized, these tissues had a distinct antitoxic value. An exceedingly interesting fact was that other complex proteid poisons besides those of bacterial origin produced effects very similar to the latter, and could induce the production of antitoxins.

Passive Immunity.—Passive immunity differed from active immunity in that in the former the free antitoxins introduced into the blood were not replaced by a fresh supply, but were gradually eliminated. In order to obtain a curative result from the use of antitoxins, it was necessary to use much larger quantities than were required to confer passive immunity. It was possible that a toxic radicle might leave a side-chain, which was already partially satisfied by union with a central nucleus, to unite with similar side-chains when they were present in a sufficient abundance and in a free state. The antitoxic character of immunity, and of immunity to infection, though closely related, were two distinct conditions. An animal might be inoculated with a given species of bacteria and not suffer because the bacteria were killed or could not develop, and yet the animal might be susceptible to the toxins produced by these same bacteria. This side-chain theory seemed to the speaker to explain more satisfactorily than other theories the subject under discussion.

Tuberculins and their Use.—DR. E. A. DE SCHWEINITZ, chief of the biochemical division, Bureau of Animal Industry, United States Department of Agriculture, at Washington, D. C., read a paper on this subject. He said that two different preparations passed under the general name "tuberculin," and were respectively designated as "old tuberculin" and

"TR." The old tuberculin was prepared by using a culture medium consisting of ordinary beef broth, salt, peptone, and from five to seven per cent. of glycerin, and inoculating it with tubercle bacilli. The cultures were then allowed to grow in a thermostat for several weeks until the germs had become well developed, and then the flasks containing them were placed in a sterilizing oven and heated for about half an hour to a temperature of 120° C. They were then removed from the oven and heated to the boiling-point, and, while boiling, were filtered. The filtrate was concentrated over a water-bath. This tuberculin contained the materials used in the preparation of the culture media, the products of the growth of the germs which had passed into solution during their development, and also those products which had been retained within the cell walls, and which had been extracted during the preparation of the tuberculin. The newer tuberculin, or "TR," contained, on the other hand, none of the materials entering into the composition of the culture media, but only the cell contents which had been produced by the growth of the bacilli, and had not passed through the cell wall into the media. The old tuberculin was a solution containing a number of foreign substances in addition to the poisons of the germs, whereas "TR," or "tuberculo-plasmin," as it was sometimes called, was a solution of the substances which had been produced within the cells as the tubercle germs developed. In the new tuberculin the contents of the germ cells had never been raised to a temperature sufficiently high to destroy the germs or affect in any way the products, and, in this respect, differed very markedly from the old tuberculin. Brieger, the chief of staff in Koch's laboratory, had made the assertion only a few months ago that the old tuberculin was not without some value. The following conclusions regarding the old tuberculin seemed to be warranted: (1) It apparently had a decided curative action for lupus; (2) It was a valuable diagnostic agent, both in animals and in man, and it should be used very much more extensively than heretofore in diagnosing incipient cases. Beck, of Berlin, reports that from 1891 to 1897, out of 4,254 patients admitted to the Institute for Infectious Diseases, 2,508 received the tuberculin injections. Of these, 1,525 reacted. If 371 cases, including phthisis, bone tuberculosis, and lupus were deducted, which could have been easily diagnosticated without tuberculin, there remained 1,154 cases in which the diagnosis had been determined by the use of tuberculin. Such a result certainly warranted the belief that tuberculin should always be used by skilful hands in diagnosing disease, and in determining if the disease had been arrested or cured. Tuberculin TR might contain in much smaller quantity than the old tuberculin what was known as "the necrotizing substance." This being the case, different results were to be expected from its use than from old tuberculin in producing immunity in animals and man. In the experiments that he and his associates had been conducting for some years, the animals had been uniformly treated with a solution of the germ entirely free from the culture media. It seemed to him that the results obtained with these tuberculins indicated that in the incipient stages the disease might perhaps be arrested, and partial, if not permanent, immunity secured by injecting into the patient the products of the bacilli, provided these had been freed from the necrotic principle already referred to. Such a serum could be readily obtained if the extract was made from attenuated instead of from virulent germs.

Antipneumococcus Serum.—Dr. Alexander Lambert, in this paper, referred to the use of this serum in pneumonia. Comparing the pneumococcus serum with those of diphtheria and tetanus, it would be found, he said, that it had a different action in the body. This serum was antitoxic, neutralizing the toxin absorbed from the localized focus of infection. This serum was not bactericidal, but bacteriolytic. The serum alone had no effect on virulent cultures of the pneumococci, but when the pneumococcus serum and the leucocytes from immune or non-immune animals were mixed with the cultures the leucocytes in a short time became filled with the germs. For this reason this serum alone could not bring the infective process to a close. The blood-vessels surrounded the exudate, and absorbed from it the deleterious products of the myriads of cocci. This germ was a septicæmic germ, and tended to invade the system and produce a general infection. There was a physical limit to the amount of protection that any serum would give. Any pneumococci left alive had the power to increase in number and augment the toxin, thus necessitating the use of more and more of the serum. If a certain leucocyte could destroy six or eight germs, and could neutralize the toxins of these germs, it might take into itself other germs whose toxins it could not neutralize, and hence be itself destroyed, allowing these organisms to continue their growth. Dr. Lambert said that the serum he had used had been obtained from horses, and it would invariably protect when 0.1 c.c. was mixed with 1,000 cc. of culture and injected subcutaneously. This serum in the laboratory would invariably protect the animal against a subsequent dose of a culture not overwhelmingly large, but if the cocci were already present in the blood, even several large doses of the serum would not save the animal, though it would prolong its life. He had used this serum in twelve cases, with nine recoveries and three deaths. The serum seemed to cause a slight reduction in the temperature and improvement in the pulse, but it did not bring on a crisis in any case, or cut short the pneumonic process. In one patient it caused a disappearance of the pneumococci from the general circulation, though it did not prevent the development of an empyema. This patient eventually made a good recovery. In two alcoholic cases the serum had had absolutely no effect, and both cases had terminated fatally. He had not persisted in the use of the serum because he could not see that it shortened the disease or held in check the pneumonic process. It had seemed to do good in one or two cases only. In certain cases it did seem to prevent a general pneumococcus septicæmia.

Diphtheria Antitoxic Serum.—Dr. W. H. Park read this paper. He said that when a minute quantity of diphtheria antitoxin was mixed with a quantity of toxin it completely neutralized the toxin in about twenty minutes. Recent investigation seemed to prove that the antitoxin acted in the body on the diphtheria poison. Its action was to neutralize the toxins in the blood, not to heal cells already injured by the disease process. Secondary pneumonia and septicæmia came, as a rule, only after the diphtheria poisons had prepared the way for such infection by injuring the body cells. This was another argument in favor of the early use of diphtheria antitoxin. Diphtheria presented peculiarly favorable conditions for the application of serum therapy, for we were in possession of a strong antitoxin, and the diagnosis could be made early. According to the records of New York City, in the pre-antitoxin days, about every sixth year the deaths from diphtheria amounted to 3,000, and would then gradually diminished to 2,000. For the fifteen years prior to the introduction of diphtheria antitoxin, the average number of deaths annually from diphtheria was 2,373, the highest number having been 3,287 in 1881, and the lowest 1,653 in 1883. In the year next preceding the introduction of antitoxin, or 1893, the deaths had been 2,870. In the last four years, during which diphtheria antitoxin had been quite generally used, the average number of deaths had been 1,341 annually, or more than 1,000 less than the average for the previous years. The same remarkable decrease in the average number of deaths had been noted in all parts of the world in which diphtheria antitoxin had been extensively employed. Statistics made it very clear that the death rate rapidly rose in those cases in which it was not given until late in the disease. Regarding immunizing injections he stated that from January 1, 1895, to January 1, 1900, 6,500 cases had been immunized by the board of health. Twenty-eight cases had developed in the first twenty-four hours, and all had resulted in recovery. After twenty-four hours and within thirty days, twenty-seven patients had developed the disease, and all of these had recovered. The only one dying within one month was a case of scarlet fever and diphtheria, dying in the first two or three days of the sickness. About three per cent. of the persons injected had shown rashes, and about five per cent. febrile disturbance. In several the symptoms had been quite distressing for twenty-four to forty-eight hours, but in no instance had any permanent injury been done. The average mortality in the Willard Parker Hospital before the use of antitoxin had been thirty per cent.; since its use, twenty-three per cent.

Dosage of the Serum.—The serum should be clean-looking and sterile, and should not be over six months old. Old antitoxin contained nothing objectionable, but it did not contain the original quantity of antitoxin, and hence the dosage must be very uncertain. Other things being equal, the higher grades of serum were better and more convenient than the lower ones. There was still some difference of opinion among observers regarding the dosage of antitoxin. In cases seen early and presenting a mild onset, he would recommend a dose of 1,000 units; in cases seen early but having severe symptoms, the dose should be 2,000 to 4,000 units; in cases seen late but apparently mild, 1,000 to 2,000 units should be given; in severe cases showing necrosis, swollen glands, and laryngeal stenosis, 3,000 or 4,000 units was the dose. The local disease should not extend after the administration of a sufficient dose of antitoxin; the swelling and hyperæmia should lessen and the constitutional symptoms should abate within twelve hours after the injection. If this did not occur, the dose should be repeated, and, in rare instances, even a third dose might be required at the end of another period of twelve hours. In a child under one year he would advise more than 3,000 units in the severest cases, and in a child of six months or under, not over 2,000 units. In a small percentage of cases diphtheria antitoxin had produced very unpleasant but, so far as known, not serious symptoms. In closing, he would recommend the use of the antitoxin in all suitable cases for immunization. It guaranteed immunity for at least two weeks.

Yellow Fever Antitoxic Serum.—Dr. Alvah H. Doty, health officer of the port, being unable to be present, sent his associate, DR. CHARLES B. FITZPATRICK, who presented the results of their use of this serum at the quarantine station. He said that the serum prepared from the bacillus icteroides had been used on a dozen or more selected cases, and had apparently exerted no controlling influence upon the disease. The same strength of serum had been used as that employed by Sanarelli. Eleven cases had been treated at New Orleans by a physician, using the Sanarelli serum, but no curative effect from it had been noted. Professor Lutz, of Santos, had carefully investigated this subject, and had also been unable to observe any curative effect from this serum. The use of the prophylactic fluid, prepared by Haffkine's method from the bacillus icteroides, had given favorable results in animals, but had not as yet been tried on man. The serum therapy of yellow fever, therefore, was still in the stage of investigation, and one was not warranted in drawing any conclusions other than that the blood serum of the bacillus icteroides of Sanarelli did not cure or modify the disease, and that further investigation was necessary.

Typhoid Serum.—DR. WILLIAM H. WELCH, of Baltimore, sent a communication stating briefly his views on this subject. Concerning the value of this method of treatment, he stated that it did not appear to him that we had at present any satisfactory experimental or clinical evidence in support of the opinion that this method of treatment was beneficial, but there was a fair experimental basis to justify, under proper circumstances, the use of the vaccine which had been introduced for the prevention of typhoid infection. The data were as yet insufficient, and for manifest reasons extensive and prolonged observation would be required before any conclusion could be reached. Such evidence as was now in our possession was sufficient to encourage a continuance of this prophylactic measure.

Antirabic Serum.—DR. ROBERT J. WILSON, of the board of health, read a brief communication on this subject. He said that the method consisted in giving the animal to be immunized seventeen injections in a period of twenty days, and, after twenty-five days, collecting the serum in the usual way. The immunizing dose was one part of the serum for every twenty-five thousand parts of body weight. Much had been claimed for this method, but there were good reasons for doubting the genuineness of these claims. The serum might, however, be useful in those cases in which a long time had elapsed between the infection and the commencement of treatment. The best method of preventive inoculations failed completely after the advent of symptoms, and here the serum might possibly be of benefit. The serum, unlike the attenuated virus, conferred its protective action immediately.

Antistreptococcus Serum.—DR. H. LILIENTHAL read this paper. He said that no case which he had observed had ever resulted in recovery when streptococci had been clearly demonstrated in the blood. Recovery, however, was by no means common when staphylococci, even in the blood, were the offending germs. In his earlier cases the dose of the serum had probably been far too small. Not less than 20 c.c. of the serum should be used. Troublesome urticaria had followed the use of the serum in a number of instances. Abscesses containing streptococci had appeared at the site of the injections in one case in which the germs had been previously demonstrated by blood culture. The serum in this instance had been procured from the New York board of health, where it had been carefully tested and proved sterile. The case was one of general sepsis, following amygdalitis and cervical abscess. The only fairly constant effect of each dose had been a temporary lessening of the delirium. Whenever there was severe sepsis with a visible cause, the first thing was to remove or thoroughly drain the contaminating foci. The sediment from the urine obtained by catheter should be stained for bacteria and examined. The discharge from the wound should be smeared upon a slide and examined with the microscope. Cultures should be made from the wound discharges and from the blood. If streptococci were found in the urine, the serum treatment should be at once instituted in addition to the proper local measures. If streptococci were found in the wound discharges, and not in the urine, it was better to await the result of the blood culture test, treating the patient meanwhile on general principles. So far the efficacy of the serum had not been proved. Antistreptococcus serum might be used in any case of bad sepsis when the exact bacteriological diagnosis was in doubt, but never to the exclusion of other rational therapy.

Serum Containing Mixtures of the Toxins of Erysipelas and Bacillus Prodigiosus.—Dr. William B. Colev presented this paper. He said that his recent experience had given no reason for changing the conclusions advanced in his earlier papers. He still used the mixed unfiltered toxins of erysipelas and bacillus prodigiosus, made from cultures grown in the same bouillon. In patients much reduced in strength, and in children, it was safer to use the filtered toxins. The dose depended very largely upon the vascularity of the tumor and the condition of the patient. The initial dose should seldom be larger than half a minim. The injections should be made into the tumor itself, and should be repeated on alternate days, or sometimes every day. The temperature reaction should not be allowed to rise above 103° or 104° F. If within three or four weeks improvement was not noted, it was hardly worth while to continue the treatment. These toxins could be given at short intervals for a long period of time without harm. In a few instances they had been administered for three or four consecutive years. He believed that the action of these toxins furnished additional evidence in support of the infectious nature of cancer. Eleven of his successful cases had been of the spindle-cell variety, and four of the round-cell type. In a former paper he had detailed thirty-five cases more or less successfully treated by other surgeons, in twenty-six of which the tumors had disappeared. In a few instances the patients had been known to be alive six or eight years after the treatment. He had used the method in two hundred and thirty cases, with only two deaths, and these two deaths had occurred in his early experience, and in patients who had been so nearly moribund that the treatment should never have been begun.

Dr. W. Travis Gibb spoke of the use of antitoxin in diphtheria. He had used it in nineteen fully developed cases of the disease, in all of which a bacteriological diagnosis of true diphtheria had been made. Two cases had proved fatal, one of the patients having been moribund at the time he had been first seen. In this case, although the antitoxin had been given early in the disease, the latter had progressed apparently without any effect from the antitoxin. The speaker had ordinarily employed somewhat smaller doses than were generally recommended. In his experience the temperature had been markedly and permanently reduced, usually in twenty-four hours, and the extension of the exudate had been checked and its exfoliation hastened. He had never seen any unpleasant constitutional symptoms follow the use of the antitoxin, and the only local effect had been an urticaria in the vicinity of the puncture, lasting for a day or two.

Dr. S. A. Knopf said that it was certainly most difficult to determine the true value of tuberculin in the treatment of pulmonary tuberculosis, because no physician would feel justified in treating this disease with tuberculin alone, neglecting all those measures well known to be useful. He failed to see that any figures had been presented pointing definitely to the curative or beneficial effect of this treatment. He had tried the antistreptococcus serum in a few cases, but had not felt that the results were sufficiently definite to justify conclusions regarding its value.

Varicose Ulcer.—The excellent results obtained in mal perforans by elongation of the plantar nerves have led Dr. Chipault (*Le Bull. Méd.*, November 4th) to extend this procedure to the relief of obstinate varicose ulcers of the leg. In five cases he has had complete success, two patients being well after an interval of two years. The most frequent indication is for elongation of the musculo-cutaneous, associated or not with that of the internal saphenous.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting March 26, 1900.

George B. Fowler, M.D., President.

Senate Bill for the Prevention of Cruelty to Animals.—This bill had been sent to the committee of the United States Senate for action. It was the bill that sought to place restrictions upon experiments on animals, and was calculated to hamper the advance in, and imparting of, knowledge indispensable to science. It was resolved that the Medical Society of the County of New York protest against the favorable report of this bill.

Some of the Reasons Why the Surgical Treatment of Nasal Disease Had Been Placed upon a Conservative Basis.—Dr. Clarence C. Rice believed that specialists were hampered by certain limitations. One of the reasons why surgical operations upon the nose and throat had been modified in frequency and character was that the specialists were better educated and were taught that no one portion of the economy could be considered apart, *i.e.*, independently of the body as a whole. The difference in nasal operations to-day as compared with those in the earlier days was due to the kind of instruments advised at the different periods. A few years ago tissues which were the seat of vascular swellings were thought to be suitable for the use of the snare, hence the turbinated tissues were encircled by the cold wire and removed. This was a temptation for physicians to perfect themselves in the use of the snare, also in the use of the galvanocautery, as well as of drills and trephines. The injudicious use of these instruments injured the specialists. Some specialists were operating all over the country. At the daily clinics the use of these instruments was demonstrated. Men became infatuated with the desire to become nose and throat specialists. This infatuation he thought was now rapidly waning. The nasal cavities in the anterior parts were so easily reached that much surgical work was encouraged. This was really the source of much trouble. A large proportion of cases of nasal swelling formerly supposed to be characteristic of hypertrophic rhinitis were really due to irritation from other parts of the chambers, and the passive hyperæmia was due to disease of organs of the body quite distant. It was difficult for rhinologists to determine whether the swellings in the nose were due to causes remote from the respiratory tract or not. Etiological factors should be recognized. Before the use of cocaine it was impossible to determine whether these swellings were due to remote or local causes. Men got bad reputations from the distressing constitutional disturbances, due to septic absorption, which followed surgical work on the nose; to-day this was not true. Nasal surgery had been greatly improved by the use of formaldehyde preparations, and greater cleanliness. The etiology of nasal disease was now better understood, and so operations were less frequent and smaller amounts of tissue were sacrificed. With proper treatment many nasal difficulties now disappeared without surgical interference. Alcohol and tobacco were powerful factors in causing nasal disturbances. Operations upon persons accustomed to their use were followed by a dry, atrophic condition; often a traumatic dry rhinitis was caused. He believed that swellings at the posterior ends of the turbinated bodies, whether composed of dilated blood-vessels or not, depended upon anterior obstructions and would disappear when the septal deformities were removed. The results of surgical treatment in the field of rhinology were far better to-day than years ago; this was due to the increased knowledge and a clearer understanding of the etiology of nasal affections; and operators had a greater desire for conservatism.

Dr. Beverley Robinson said that a few years ago the general conditions of the body, different diathetic influences, the habits, surroundings of the patient, etc., were supposed to be more important than any local conditions found in the nose. The judgment formed by him twenty years ago he still retained. At one time a great many men made skilful use of these instruments, and they found they could take away tissue with relative impunity; a time came, however, when accidents followed these nasal operations. Sometimes these accidents happened during the operations, and sometimes they occurred subsequently. A certain number of nasal affections required the physician only, and others remained within the province of the surgeon. When an operation upon the nose of some moment was required, previous training was very essential. Unfortunately a number of men were going into this specialty, and this fact caused him considerable dread. The majority of young fellows, he thought, could make a fair diagnosis, but they did much harm. Advice should be given only by thoroughly trained men, those who have had opportunities of learning what to do and knew how to do it, who have had such previous education as to render them fit to work without doing harm by useless interference. He hoped to remain long enough in the Academy of Medicine to see every general practitioner control every specialty in the land, and to tell one how far to go and that he should go no further. The dermatologist thought the human body could not be right unless the skin was right; the rhinologist thought that the body could not be right unless the condition of the nose was correct; and so with every specialty. He wished to convey the idea that it was impossible for a man in any specialty, no matter how trained, not to take an exaggerated view of his own work. He advocated common "horse sense."

Dr. W. C. Phillips thought the remarks on an unqualified specialist were out of order in connection with any medical discussion. All present knew that a little knowledge was dangerous in any department of medicine. Many who worked in this region of the body had come to the conclusion that simply because they looked into the nose and found a swelling over the turbinated bone, or a congested septum, surgical interference was necessary. These conditions were very frequently, in his opinion, symptoms of some disease in a remote part of the body. He wished to emphasize the point that no specialist could attain great proficiency without having had large experience as a general practitioner. Only that day a patient had been sent to him to have a nasal polypus removed; the patient had an atrophic rhinitis and slightly swollen tonsils, but required no surgical interference because he had no polypus. The speaker referred to disturbance of the gastro-intestinal tract as a causative agent in certain diseases of the nose and throat; he thought this was one of the most common causes of nasal symptoms. The over-use of alcohol and tobacco entered largely into the causation of nasal troubles. He looked upon the presence of "colds in the head" in many individuals as something else than exposure to draughts and other causes. Two patients might be dressed about alike, and go out on certain days, using great care to prevent taking cold, yet one would catch cold and the other would not: why? He believed the exciting causes here were over-work and lack of rest, or fatigue. Again, he believed that there were many pathological conditions in the nose that could be relieved only by surgical interference. When certain conditions which caused the patient suffering were found and removed, he called that conservatism.

Dr. Francis J. Quinlan emphasized the importance of removing the cause and not the effect of diseased conditions. He referred to certain dyscrasiæ or diatheses, especially the syphilitic and tuberculous. Prophylaxis was something in the reach of everybody, and he considered the greatest of all such measures water, both without and within; sunshine, air, and exercise. These four factors could destroy more disease than could anything else. If one destroyed the turbinals, he thought one destroyed the portal to the lungs. In the study of many of these conditions "knowledge came but wisdom left."

Dr. Emil Mayer said it was not generally known how many sins the general practitioner had to answer for in the use of the electro-cautery; a large percentage of the work done by rhinologists was in correcting the work done by the general practitioner in the use of this instrument. In the nose, the use of the electro-cautery was very limited. He believed that any work done was worth doing well, and therefore he never performed the simplest operations without using the most rigid aseptic details, with a trained assistant and trained nurse.

Dr. David Goodwillie referred to the importance of a knowledge of the physiological processes concerned in respiration. The gateway to the nose was very important. The mucus in the nose was of use in keeping the nasal membrane from becoming dry, and the extra amount of it protected against irrespirable gases or bad air. He had great respect for the mucous membrane of the nose, which covered so large a surface in so small a space. In the treatment of diseases of the nose he believed we should be more careful in saving the muciparous glands. He never forgot the experience of a friend of his, who went to a rhinologist, who removed hypertrophied tissue and the mucous membrane covering it; his friend has since wished he had never gone, on account of the ease with which he "caught colds." Much injury was done to the Eustachian tubes and the pillars of the palate by bad surgery.

Dr. Rice, in closing the discussion, said that every man was entitled to breathe through his nose, and if the occlusion in the nose was permanent, it must be relieved, and the nasal surgeon was competent to do this, in a conservative way. A great many cases must be operated upon no matter what the source of irritation was. The specialist could help the general practitioner, even in cases of intestinal catarrh; here he could help by curing the existing upper catarrh, and so preventing the patient swallowing the mucus and pus.

The Requisites of the Modern General Practitioner; his Relation to the Community and to Specialism.—Dr. Augustus Caillé read this paper. He said the time was in the memory of all present when the family practitioner was a trusted counsellor. The introduction of general and local anæsthetics, asepsis and antisepsis, and serum therapy, etc., gave such opportunities of diagnostic and therapeutic possibilities that one could not grasp them all. The introduction of cocaine had been followed by rapid development of the nose specialist. Bacteriological and chemical research gave such a complexity of terms, and an avalanche of literature that completely swamped the ordinary medical man, and he could not keep abreast with the times. These vast strides made the position of the general practitioner a peculiar one; every young practitioner felt superior to the older ones. To what extent should we encourage young men and women to take up the practice of medicine for a livelihood? It would appear that medicine was looked upon as a promising field. That was not so now if the existing conditions were studied. During the past ten years the profession had been overcrowded; there had been a production of medical men far above the demand.

He advised that no one should enter upon this career without appreciating the difficulties to be overcome and the hard work and drudgery that were entailed. Competition was a strong master; it elevated and degraded. He then briefly discussed what was the place in society of the family practitioner, and under what conditions he would be in demand. He did not believe that the family practitioner was to become extinct, for two reasons: first, many intelligent people would refuse to give up a good practitioner; second, the public had already largely and seriously suffered by indiscriminate consultations with immature specialists. Much of the specialists' operative work deserved the highest praise, yet the families turned to the general practitioner. He felt convinced that all medical men would become competent diagnosticians and formulate plans of treatment without using so many worthless drugs, and that they would do more work at the bedside. The family practitioner must (1) be master of physical diagnosis; (2) he must have some laboratory training; (3) he must be able to make local or regional examinations; (4) he must have a good knowledge of hygiene and dietetics; (5) he must be able to perform minor surgery as well as emergency operations; (6) when feasible, obstetrical cases should not be handled by the general practitioner. The difficulties of making correct diagnoses were not great if one went about it in a systematic way. For some years past he had used diagnostic charts, which he found to be a great help in making and recording diagnoses in the office and at the bedside, or in hospital. The reasons why the general practitioner should not attend obstetrical cases were two in number: first, it was usually night-work, and the physician who worked from 10 A.M. to 10 P.M. should go to bed; second, he was at all times in contact with contagious or communicable diseases, and so might infect the parturient woman. He condemned the hurry and bustle of the present life; it was all wrong. The general practitioner, in his opinion, was not sufficiently paid for the work he did. To counterbalance the loss of fees from obstetrical work the general practitioner would have more time at home and in his family, and more time and ambition to practise minor surgery. He believed that minor surgery belonged to the general practitioner; if he had no surgical training, he was handicapped from the beginning. The knife in conservative hands gave much relief. Rheumatism, typhoid fever, tuberculosis, pneumonia, diabetes, and other so-called medical diseases often presented complications requiring surgical knowledge. Pure surgical cases frequently developed non-surgical complications. A simon-pure prescription writer had no future in practical medicine. Yet he believed that every man should know his limitations in doing surgery. In country practice, he advised that the neighboring doctors should combine and help one another in doing surgical operations. He thought that nurses, especially obstetrical nurses, should be encouraged to go to the country. The rural communities should be educated to the need of such service. All practitioners should become familiar with the clinical microscope. The speaker condemned the drugging habit. Books on materia medica placed a lot of therapeutic ballast in our hands. Every few weeks new drugs were forced upon the physician with the claim that they were a specific, and many physicians were gulled into trying them and were disappointed. Medical literature, he thought, was on a rampage, and he felt happy that many physicians could read but one language. The average practitioner would do well to take one good weekly journal and one or two monthlies devoted to some particular line. How else could the general practitioner keep up with progress and art? He advised country practitioners to take a post-graduate course. He did not believe that the dispensaries and hospitals were utilized as they should be; the best hospitals were teaching hospitals. Must post-graduate work be taken abroad, or could it be gotten better here? He had visited Germany, England, and France, and was familiar with the post-graduate institutions there. In laboratory work he believed that Europe was ahead of us, but not in any practical work in medicine and surgery. "Why fly to a foreign shore, when the best is at your door?"

DR. GEORGE M. EDEBOHLS thought the advice to the general practitioner was timely, as the successful ones occasionally found it difficult to determine just what course to pursue. For the first fourteen years of his professional career he was engaged in general practice; at the end of that time he was in the same dilemma that many practitioners were to-day, and could not decide whether to pursue a general practice or take up some specialty. At that time the specialists were having the best of it; they were better paid for their work; they were able to time their work, and could devote some time to occupations other than that of medicine; they could take vacations. So when the opportunity offered he embraced the career of a specialist. A young man working in the city should from the beginning work every day on some special line. He then cited an instance showing the importance of a knowledge of general medicine in following a specialty. He was called by a general practitioner of excellent reputation, of great accomplishments, who stated the case of a woman, four or five days after delivery, having puerperal fever, with a temperature of 104° F. and rapid pulse, etc. He was asked to curette the uterus, as it was desired to have the uterus emptied. He took the precaution of first examining the patient thoroughly, and he found an acute pericarditis, and nothing at all wrong with the sexual organs. Had the woman been chloroformed death would certainly have followed.

DR. S. ADOLF KNOPF said he was much impressed with what had been stated regarding materia medica as taught in medical schools; there they lacked training in hygiene and diet, especially in telling how food should be prepared. We must look to the general practitioners to combat tuberculosis, because they saw the incipient cases. To them we must turn for detecting early tuberculosis.

Medical Items.

Review of Surgery for the Past Hundred Years.—Mr. H. G. Howse ends his elaborate review of surgery during the last one hundred years, delivered before the Royal College of Surgeons of Great Britain, on December 13th, with these words: "And yet while wondering at and admiring all the great advances of the last one hundred years, while hoping for similar great advances in the future, while urging our pathologists and bacteriologists to pursue these investigations which may have such an important influence upon the treatment of disease in the future, it may be wise to add a word of warning. There is a tendency in making these complicated investigations to conclude too much from a single instance. Very grave errors will arise in the conclusions of the future unless investigators will guard themselves most carefully from this error. In other directions we are all apt to become too dogmatic in our views, which are based on indisputable facts—views, however, which on further examination we find it necessary to modify in accordance with our increasing knowledge and experience. Nowhere is this shown more strikingly than in the rapid changes of antiseptic and aseptic details in the treatment of wounds which have chased each other like cloud-shadows across our surgical stage during the last twenty years. It may reasonably be doubted how far some of these details are really scientific and how far they are mere fads. I would conclude this lecture, then, by quoting an admirable saying attributed to the late master of Trinity College, Cambridge: "We are none of us infallible; no, not even the youngest of us."

Confectionery in Army Rations.—The Germans about ten years ago introduced the use of candy into the diet of their soldiers. The idea was the outcome of experiments undertaken by the German government. It was demonstrated that the addition of candy and chocolate to the regular ration greatly conduced to the improvement of health and endurance of the troops, and at the present time the army authorities in Germany issue cakes of chocolate and a limited amount of other confectionery. The British were the next to follow this example, and the queen, as has been extensively advertised, forwarded five hundred thousand pounds of chocolate in half-pound packages as a Christmas treat for the soldiers in South Africa. Jam has also found great favor with the British War Office, and 1,450,000 pounds have been dispatched to South Africa as a four months' supply to 116,000 troops. The United States is following in the same path, and candy has been added to the regular army ration of the American soldier. It is stated that one New York firm has shipped more than fifty tons of confectionery during the past year for the armies in the Philippines, Cuba, and Porto Rico. The candy supplied is of excellent quality, consisting of mixed chocolate creams, lemon drops, cocoanut maroons, and acidulated fruit drops. These are packed in tins specially designed to fit the pockets of a uniform coat. The question of providing jam with the army ration is also under consideration.

Insects as the Cause of Contagion.—The rôle taken by insects as vehicles of contagion assumes every year a more important position in the estimation of clinical observers. It is exceedingly probable that the common house-fly was the carrier of contagious material from wound to wound in the days when hospital gangrene prevailed in epidemics. The initial case was usually one of syphilitic phagedæna, and the flies did the rest. The same might not improbably be the case in many instances of hospital erysipelas. In purulent ophthalmia as observed in hot climates and in the army, and to less extent occasionally in English practice, flies no doubt were the chief agents in its spreading. In the epidemics of school ophthalmia they are again to be suspected. The spread of the ague germ by means of mosquitos is now an established fact, but here we have an instance of the parasite breeding in the tissues of the insect and not of its mere transference. The suggestion that mosquitos are a means of contagion in leprosy has had its advocates. It is, however, I think, conclusively negatived by the fact that of the European immigrants into leprosy districts scarcely any contract the disease.—JONATHAN HUTCHINSON'S "Archives of Surgery."

Seats for Shop Assistants in Great Britain.—The "Act to provide for seats being supplied for the use of shop assistants," which received the royal assent on August 9th, this year came into force on January 1st. The act is short—it only contains four sections; so "Ignorantia legis neminem excusat" specially applies in this case. As the first two sections, which contain all the necessary information on this new piece of legislation, do not occupy many lines in the statute book, it will not be out of place to set them forth verbatim. The first section describing the scope and effect of the new law provides that "in all rooms of a shop where goods are actually retailed to the public, and where female assistants are employed for the retailing of goods to the public, the employer carrying on business in such premises shall provide seats behind the counter, or in such other position as may be suitable for the purpose, and such seats shall be in proportion of not less than one seat to every three female assistants employed in each room." The second section deals with the penalty for non-compliance with the above provisions. The last section states that the new act is to be construed and read as one with the Shop-hours Act, 1892 to 1895, or, in other words, the provisions of these acts, in so far as they are not inconsistent, are to apply to this act. The Shop-hours Act places a limit on the number of hours during which young persons under eighteen years of age may be employed in a week.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 31, 1900:

		Cases.	Deaths.

DIFFUSE SEPTIC PERITONITIS, WITH SPECIAL REFERENCE TO A NEW METHOD OF TREATMENT, NAMELY, THE ELEVATED HEAD AND TRUNK POSTURE, TO FACILITATE DRAINAGE INTO THE PELVIS. WITH A REPORT OF NINE CONSECUTIVE CASES OF RECOVERY.[1]

BY GEORGE R. FOWLER, M.D.,
NEW YORK,
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

THE peritoneum is virtually an enormous lymph sac, and therefore peritonitis is lymphangitis. The absorbents of the structure of the peritoneum are represented by the lymphatics, and the protection which these afford against infecting agents by exudative material thrown out (thrombo-lymphangitis) to act as a defensive barrier by blocking the lymph channels serves to preserve the life of the subject, on the one hand; while a failure in this respect, either because of the enormous and overwhelmingly rapid increase of septic material and the large size and number of channels necessary to destroy or obstruct, on the other hand, permits the destruction of the organism. Hence rapidly proliferating bacterial invasion means more or less absorption, perhaps sufficient to destroy life, before proper protection has been afforded in the manner mentioned. Or, on the contrary, a slow proliferation permits of the formation of exudative barriers to the extent of arresting further absorption and saving life.

The bacterial fluid present in a case of peritonitis is a transuded fluid, which, in the process of transudation, forces the endothelial cells from the peritoneal lymphatic surfaces; the desquamated cells, together with leucocytes and other cell-forms, floating about in the fluid. In cases of recent origin flakes of lymph are also present in the fluid. Patches of a coagulated albuminous substance, the result of the exudation of an albuminous fluid from the lymph channels and of fibrin from the blood (fibrinous exudate), appear as a soft, reddish-gray substance more or less adherent to the peritoneal surfaces, and here and there bridging over the spaces between adjacent coils of intestine, through the medium of which they adhere together.

The infecting agents also present in the fluid are invaders to be gotten rid of or prevented from proliferating and exerting their baneful effects, through the medium of the larger leucocytes, or macrophages of Metchnikoff, which migrate to the peritoneal cavity for this purpose. In order to effect their purpose these must come in contact with the microbes, either investing the latter to imprison and sterilize them, or checking their movements by simply adhering to them. The presence of a large quantity of fluid in the cavity of the peritoneum must necessarily interfere greatly with this contact between the leucocytes or macrophages and the invading and proliferating bacteria, since the contact, under these circumstances, must be more o less infrequent and of an accidental character. It is now believed that one of the functions of the omentum is to bring about this contact by its movements in the peritoneal cavity causing the bacteria to adhere to its surfaces, where they are readily attacked by the leucocytes. This view is supported by the clinical fact that whenever a focus of infection exists in the peritoneal cavity, there are more than likely to be found omental folds, reaching out, so to speak, for the bacterial intruders and becoming adherent to the peritoneal surfaces adjacent to the focus during the process.

Not all of the regions of the peritoneum possess the physiological power of absorption to the same extent, for the reason that certain anatomical differences preclude this. For instance, the portion possessing this in the highest degree is the region of the diaphragm, where large lymph trunks are present, the open mouths or stomata of which stand ready to take up and transport to the system at large whatever fluid with its contained pus, blood, bacteria, or toxic products of the latter, may present itself. The size of both lymph trunks and stomata in this region is such as to prevent their early or rapid obliteration through thrombo-lymphangitis, and hence the organism may be destroyed through the widespread distribution of septic material before this can occur. This is particularly true of that portion of the region of the diaphragm known as its central or tendinous portion.

The region in which the anatomical conditions favoring rapid absorption exist in the next highest degree is the intestinal. Here there likewise exist large lymph trunks and stomata, but not to the same extent as are found in the region of the diaphragm. These are, however, sufficiently numerous to render this region a dangerous area of absorption.

Turning now to the remaining region, namely, the pelvic, we find that the non-absorptive character of the peritoneum is apparent. Microscopical study of this portion of the peritoneum reveals the fact that, while it is rich in capillary lymphatics, large lymph trunks and stomata are comparatively absent. The smaller lymph vessels of this region become much more rapidly obstructed, and hence absorption from this region proceeds very slowly, and finally ceases altogether, the arrest being coincident with plugging of the capillary lymph vessels with lymph thrombi, the result of infection and consequent inflammation of the lymph vessels themselves, aided by pressure from without, the latter resulting from peri- and paralymphangitis. This cessation persists until the toxic properties of the contents of the pelvic cavity are either destroyed or neutralized, when absorption is resumed through some, but not all, of the vessels. Many of the latter remain permanently closed. The latter circumstances correspond to the clinical fact that in some patients many attacks of pelvic peritonitis result in the formation of chronic exudates, due to the inability on the part of the absorbents to remove the latter, at least for a long time.[1]

---

[1] Read before the Brooklyn Surgical Society, March 1, 1900. Enlarged and revised since its first presentation.

[1] See the able presentation of the facts bearing upon this subject by Dr. Byron Robinson, of Chicago, in an article entitled "The Pathology of the Lymphatics of the Peritoneum," in the Annals of Surgery, vol. xxxi., No. 2, p. 214.

It is likewise probably true that a certain immunity is conferred upon the peritoneal structure of the pelvis through previous attacks. And inasmuch as invasion of the pelvic cavity may readily occur through fecal stasis in the adjacent rectum in both sexes, and through the open mouths of the Fallopian tubes in the female, it is fair to assume that a certain degree of immunity or non-susceptibility is possessed by the peritoneum in that region through the permanent closure of its lymphatics, which is not shared by that in the other regions.

Reasoning from the facts above set forth, the practical surgeon should be able, in support thereof, to bring to bear evidence that the pelvic peritoneum is less liable to become the seat of danger in cases of septic invasion of the latter. He should be able to show, first, that the pelvic peritoneum possesses a certain degree of non-susceptibility to bacterial invasion; second, that when this does occur the spread therefrom is sufficiently slow to permit of the formation of exudativ barriers protecting the more susceptible enteronic and diaphragmatic areas; and third, that the occurrence and retention of large quantities of septic fluid in the pelvic cavity do not give rise to the symptoms reterable to the system in general characteristic of the presence of such fluid in the cavity of the peritoneum. In support of this contention that these requirements are successfully met by clinical experience, the following is offered:

It has long been noted by surgeons that septic inflammatory processes when confined to the most dependent portion of the peritoneal cavity remain quiescent and without urgent symptoms for quite a period of time, as compared with a like condition of affairs existing in that portion of the peritoneal cavity situated above the pelvis. The facts that puerperal infection occurs with comparative infrequency in the large number of cases of labor among the poor, attended by those but little if at all acquainted with aseptic methods; that this, when it does occur, extends to the general peritoneum in a relatively small proportion of cases in which the peritoneum of the pelvic region is involved; and, still further, that infective processes in this region do not, as a rule, give rise to the same grave symptoms as an equal area of peritoneum infected in the abdominal cavity—still further suggest the theory that the peritoneum in this region is possessed of qualities which enable it, first, to resist infection; second, to limit the infection within its own area when it does occur, and third, either so to modify the virulence of the infection or to resist the absorption of its toxic products as to prevent, in the great majority of cases, the grave constitutional symptoms characteristic of an equally extensive infection of the peritoneum above the pelvis. These qualities are still further emphasized by the fact that operative procedures involving the pelvic peritoneum performed by the vaginal route, conducted as they must necessarily be in close proximity to a region difficult, if not impossible, of even relative disinfection and isolation, namely, the anal region, seem less liable to be followed by septic peritoneal inflammation than the same procedures conducted by the abdominal route. In the case of suppurative salpingitis, at least, it cannot be urged that this comparative immunity is due to the non-entrance of septic or pyogenic micro-organisms, since, in order to remove the parts involved, it becomes necessary to break down limiting adhesions; in some instances rupture of the walls of abscess cavities occurs as well, thus leading to contamination of the surroundings in spite of a preliminary aspiration of the contents. Yet the patient escapes the peritoneal inflammation which so frequently follows when invasion of the general cavity of the peritoneum by the pus occurs, as it will in spite of every precaution.

The claim that this comparative immunity is due to the fact that the infecting organism largely concerned in pelvic inflammation, namely, the gonococcus of Neisser, is not necessarily pyogenic in character, in the cases of pyosalpinx at least, falls to the ground in the face of the experience of surgeons in those instances in which this micro-organism is sufficiently virulent to produce the metastatic joint conditions known as gonorrhœal rheumatism, which, after all, is but a variety of pyæmia. So pronounced does this joint condition sometimes become that destructive processes following this infection occur, bacterial examination of the fluids of the joint removed by operation showing the undoubted presence of the gonococcus. I am aware that a contrary view is held by many competent and careful observers, Kelly particularly, who states that, in many hundreds of bacteriological examinations made, he has never yet been able to demonstrate this micro-organism as the etiological factor in the production of septic peritonitis. It is nevertheless true that other and well-known organisms capable of producing both local and general septic conditions are destroyed after a time by the growth of other and more vigorously active bacteria, failure to identify these resulting. It cannot therefore be absolutely claimed that the gonococcus is non-infecting to the peritoneum, since the micro-organism frequently attacks the serous lining of joints. On the contrary, experience seems to prove that it has a special affinity for serous membranes, since it rarely invades by metastasis other structures. In common with many others, I at one time believed that the pus from a pyosalpinx ruptured during the removal of a gonorrhœal pus tube by the abdominal route would do but little if any harm, even if it did come in contact with unprotected intestine and thereby found its way into the general peritoneal cavity. But I have long since learned by sad experience the fallacy of this view, and while admitting that the gonococcus infection may do comparatively but little if any harm to the peritoneum of the pelvic cavity, yet I am more than convinced that its contact with that portion of the folds or reflections of the peritoneum constituting the mesentery of the small intestine is fraught with danger. At the present time my plans to prevent this accident are as well laid, and my anxiety lest it should occur as keen, as if I knew for a certainty that I was dealing with a violently infectious micro-organism.

Aside from the virulence of the bacterial contents of abscesses resulting from non-puerperal pelvic inflammation, the latter, as it arises from full-term deliveries and from abortions as well, may be considered. Here the claim cannot be made that the infecting agent is of a less virulent character than those which gain entrance to the cavity of the general peritoneum; certainly it will not suffice to say that all cases of pelvic peritonitis in the female are due to gonococcus infection. Yet how many of this class come under the surgeon's knowledge in which the septic processes are confined to the pelvis, and in which the local infection is out of all proportion to the general symptoms, in precisely the same manner as the cases indubitably due to gonorrhœal infection. And the same may be said of those cases in which the uterus is accidentally punctured during a curettage for septic conditions of the endometrium. That such accidents occur more frequently than is generally supposed, I am convinced, yet I am informed by a well-known obstetrician and gynæcologist who comes in frequent and intimate contact with those who follow especially this kind of surgical work, that these do not regard the occurrence of this class of accidents as of grave importance; not sufficiently so, at least, to warrant opening the peritoneal cavity for purposes of repair, much less for cleansing and drainage.

So too with cases of infection of the pelvic peritoneum occurring in the male—such, for instance, as the production of false passages between the bladder and rectum, and involving the recto-vesical pouch of peritoneum at the hands of careless or unskilful practitioners. In one case of this kind I opened the abdominal cavity and found the pelvis the seat of what was evidently a virulently infective inflammatory process, yet the latter was absolutely confined to the pelvis, although but few limiting adhesions were present, and these of the flimsiest character. Sufficient time had elapsed, and ample opportunity had been afforded for spread of the infection to the peritoneum, yet this had not occurred. Certainly the local symptoms possessed a gravity out of all proportion to the general symptoms present in the case.

I turn now to the cases in which opportunities for the invasion of the pelvic peritoneum by the most indubitably virulent micro-organisms, such as those escaping from the intestinal canal, are afforded. This mode and character of infection are perhaps exemplified more frequently in cases of appendicitis in which the organ points downward into the pelvis, and in which early perforative ulceration or gangrene leads to the escape of the contents of the organ. It not infrequently happens, in tracing the appendix into the pelvis, that the latter is brought up to view either perforated or gangrenous, this being followed by a gush of sero-purulent fluid, or, as sometimes happens, the presence of the latter is discovered only by passing gauze grasped in a long forceps into the depths of the pelvis; and then follows the removal of quantities of this septic fluid by the same means. I have thus removed astonishingly large quantities of this material, and yet the patient's condition, either general or local, gave not the least suggestion beforehand that such a condition would be encountered. And, unfortunately, in some of these cases the manipulations incident to the removal of the fluid has led to infection of the peritoneum above the pelvis in spite of every effort to prevent this, with the result of loss of the patient's life from diffuse septic peritonitis, the infecting material coming into contact with the general peritoneum notwithstanding every precaution of walling off the latter with a large number of gauze compresses.

It was during the after-treatment of a case of diffuse septic peritonitis the result of early perforation of a violently inflamed appendix directly into the peritoneal cavity and between the coils of small intestine, and in which I had placed a glass drain as well as a number of wick drains deep in the pelvis, that the line of thought above expressed occupied my mind. My assistant, Dr. R. S. Fowler, had been in the habit of treating cases of vomiting following etherization by raising the head of the bed as high as possible consistent with comfort, thus bringing the force of gravity to bear in facilitating normal peristalsis. In view of the favorable course which the case then in hand was pursuing, it was determined to adopt this as a routine procedure for the purpose of facilitating the passage of septic fluids from the general peritoneal cavity to that of the pelvis, where, according to the reasoning above outlined, it would do but little harm, comparatively speaking, and from which locality it could be more readily removed by drainage methods. This has been done, and a further experience with the method seems to bear out the favorable opinion first entertained of this measure as of value in aiding to combat the mortality in this much-dreaded condition.

The angle assumed has varied somewhat, but I insist that the elevation of the bed from the horizontal shall be at least from twelve to fifteen inches. In order to prevent the patient from sliding down in the bed a large pillow is placed folded beneath the flexed knees, and upon this the buttocks rest. The pillow is prevented from sliding by a piece of stout bandage passed through at the folded portion and secured to the sides of the bedstead.

The following is a list of the cases consecutively treated by this method to date:

CASE I.—October 17, 1899; Brooklyn Hospital. Diffuse septic peritonitis from a combined appendicular and adnexal lesion, originating, in all probability, in the appendix. The accessible parts of the cavity of the peritoneum were treated with equal parts of peroxide of hydrogen and saturated solution of bicarbonate of sodium, which was finally flushed away with decinormal saline solution, after which the abdominal cavity was dried out as thoroughly as possible. Two glass drains were placed in the pelvis and wicking drains inserted in these. The drainage tubes were dressed separately from the abdominal wound.

After-treatment: The head of the bed was raised and kept so for seventy-two hours. The glass tubes were cleared every two hours by aspirating their accumulated contents by means of a long pipette. Copious saline enemata were given, with the usual stimulating treatment, consisting of sulphate of strychnine and citrate of caffeine. The glass drains were withdrawn on the eighth day, and hemmed gauze strips substituted. Recovery resulted. Bacteriological examination of material taken from the remote upper portion of the peritoneal cavity at operation showed staphylococcus infection.

CASE II.—October 23, 1899; Brooklyn Hospital. The patient presented the typical clinical picture of diffuse septic peritonitis, with a history pointing to perforative appendicitis as the cause. No hope was held out for recovery, and I hesitated about operating at all. The operation revealed a perforated appendix lying free in the peritoneal cavity and a large quantity of foul-smelling sero-pus. The abdominal cavity was flushed with the peroxide of hydrogen and bicarbonate of sodium solutions, finally washed away with decinormal saline solution. The abdominal cavity was dried out, and combined glass and wicking drains were placed in the pelvis.

After-treatment: The head of the bed was raised. The tube was cleared of its contents every hour for the first six hours, then every two hours. Saline enemata, one pint, were given every hour as long as the rectum was tolerant. The ice coil was applied for relief of pain. Sulphate of strychnine in gr. $\frac{1}{10}$ doses was given every three hours. There was no vomiting until the third day, when the head of the bed was lowered; in a short time the passage of flatus, which had occurred at intervals previously, ceased, and vomiting occurred. The latter was at first bile-stained, but with rapid distention it soon became fecal. Through a misunderstanding the head of the bed was not raised again for twelve hours, at the end of which time, following a return to the elevated head and trunk posture, improvement in the symptoms commenced and was steadily progressive, so that at the end of another twelve hours the patient expressed himself as feeling comfortable. Owing to delay in the bacteriological report antistreptococcic serum was employed for the first three days, but this did not seem to exert any influence. The glass and wick drains were removed on the tenth day. Right-sided phlebitis of the saphenous vein developed on the nineteenth day. The head of the bed was kept elevated for three weeks. Staphylococcus growth was identified. The patient recovered.

The phlebitis which occurred in this case may have been due to the increased difficulty experienced by the return circulation owing to the unnecessarily prolonged elevated head and trunk posture. Sonnenburg, who has called attention to the complication of phlebitis of the veins of the lower extremity following abdominal section, advises raising the foot of the bed as a prophylactic measure.

Case III.—October 31, 1899; Brooklyn Hospital. Operation by my assistant, Dr. Russell S. Fowler; recurrent appendicitis, with diffuse septic peritonitis. The abdomen was distended and rigid, and no gas had passed for thirty-two hours. The appendix, gangrenous throughout and perforated at the tip, and containing an enterolith as large in diameter as the thumb nail, was found lying against the cæcal wall, which was likewise gangrenous. The appendix was removed and the gangrenous spot on the bowel wall enclosed in Lembert suture. A large quantity of foul-smelling pus and sero-purulent material was scattered through the peritoneal cavity. Cultures were taken from distant portions of the latter. The cavity was sponged thoroughly with dry gauze, and twenty-one wick drains were disposed throughout the cavity of the peritoneum, including the pelvis, and led out of the operation wound. After-treatment consisted in raising the head of the bed, saline enemas every hour, and large doses of strychnine. The amount of fluid which flowed from the drains during the first twenty-four hours soaked the dressings copiously, the patient's clothing, and the bed. The distention showed marked decrease within twenty-four hours, and gas passed per rectum freely and frequently. The temperature reached normal on the third day and remained so. All drains were removed by the eighth day. Both lower extremities were massaged daily to prevent blood stasis and consequent phlebitis. Bacteriological examination showed both staphylococcus and streptococcus infections, the latter predominating.

Case IV.—December 7, 1899; German Hospital. The patient was admitted with perforative peritonitis of appendicular origin, and presenting the typical picture of diffuse peritoneal inflammation. Upon opening the abdomen free sero-pus was found to be present. The peritoneum was of a dusky cherry-red color as far as could be seen in all directions, and the coils of intestine were greatly distended and covered in places with lymph. The appendix was gangrenous and perforated. The peritoneum of the abdominal and pelvic cavities was sponged clean with simple sterile gauze and all lymph deposits were removed. Gauze-drainage strips were placed in different directions, including a large drain of the same material into the pelvis, and led out of the abdominal wound.

After-treatment: The head of the bed was elevated and kept so for six days. Fluids were given *ad libitum*, as soon as the patient recovered from the anæsthetic, and of these he partook freely. There was no vomiting. Distention rapidly disappeared, gas passed per rectum, and the patient was practically beyond the period of anxiety by the fifth day. The drainage strips were removed in stages, a strip being removed each day, that from the pelvis being the last; they were all out by the eighth day. During the first three days the amount of fluid removed by the drains from the peritoneal cavity, as represented by the soaked dressings and bed, was enormous. Recovery followed. No bacterial examination was made.

Comment: This patient received scarcely any medication, the main reliance being placed upon drainage, posture, and the free ingestion of fluids. The latter was made possible by the absence of vomiting after the operation, although this had been a distressing feature before the abdomen was opened. The removal of large quantities of fluid from the peritoneal cavity through the medium of the drains was a pronounced feature of this case. I have always looked upon this as being exceedingly favorable from the prognostic standpoint. This seems to be borne out by the observation that cells suspended in fluid cannot act so vigorously as when localized in the endothelial surface, and hence cannot, when so suspended, destroy so many bacteria, not only on account of the lessened chance of encountering the bacteria, but because the latter are not so liable to adhere to the cells. With the withdrawal of the fluid the cells reach the endothelial surface, where they assert their aggressiveness upon the bacteria by their own power of movement (*vide supra*).

Case V.—December 13, 1899; German Hospital. The patient was admitted with peritonitic facies, distended and rigid abdomen, with a history of a two-days' illness and symptoms pointing to appendicitis. The onset of the attack had occurred while the patient was on her knees scrubbing the floor. No previous history pointing to the existence of a tumor or of menstrual disturbances was obtained. The operation revealed a diffuse septic peritonitis with evidences of recent rupture of an ovarian cystoma, the chocolate-colored fluid from which had invaded the cavity of the peritoneum above the pelvis. This was carefully wiped away as far as possible with dry sterile gauze, and two glass drains with wicking inserted were placed in the pelvis.

After-treatment: The head of the bed was elevated; strychnine and citrate of caffeine were given in moderate doses, with hourly enemas of saline solution. The tube was cleared by the aspirating pipette every two hours, and from a half ounce to two ounces of dark-colored serum was removed each time. There was no vomiting. Rapid improvement followed. Gas passed within six hours. The tubes were removed and replaced by gauze strips on the fifth day. Recovery was uneventful. No bacteriological examination was made.

Comment: In a case bearing a remarkable resemblance to the one narrated in all respects, which came under my care shortly before I commenced the postural feature of the after-treatment, and in which every detail of the treatment was identically the same with the exception of the elevated head and trunk position, death took place on the fifth day from steady and progressive advance of the disease and general septic infection. In fact, I have always looked with much apprehension upon cases of this character, in which the rather heavy and chocolate-colored contents of an ovarian cystoma have escaped into the general peritoneal cavity. This case will be referred to later in this paper.

Case VI.—December 15, 1899. The patient was admitted to my service at the German Hospital with a perforative peritonitis of appendicular origin. Distention and general rigidity were marked. Operation by my assistant, Dr. R. S. Fowler, revealed a perforated appendix lying free in the peritoneal cavity, and a diffuse septic peritonitis present. The peritoneum, as far as could be determined by the incision, was deeply reddened. The intestinal coils were covered in patches with lymph and greatly distended. There was a large quantity of free sero-purulent material in the cavity of the peritoneum. The abdominal cavity was sponged dry with sterile gauze, and all lymph deposits were removed. Numerous strips of iodoform gauze were placed in different parts of the abdominal cavity and pelvis, and led out of the operation wound.

After-treatment: The head of the bed was raised and left so for three days. Saline enemas were given to the extent of their toleration by the rectum, and fluids were administered freely, with moderate stimulation by means of strychnine and citrate of caffeine. The drains were removed singly and upon separate days; the last was removed on the sixth day. Recovery followed. There was no bacteriological examination.

Case VII.—The patient was admitted to my service January 24, 1900, in the German Hospital, with a history of recurring attacks of appendicitis, the last of which came on six days previously. Upon admission the usual anxious expression was visible, with greatly distended and rigid abdomen. Operation was done by my assistant, Dr. R. S. Fowler. The abdomen was opened by an incision placed at the outer edge of the right rectus muscle. Free pus was present in the peritoneal cavity, with the usual widespread and deeply reddened peritoneum. Three distinct abscess cavities were found in addition: one in the neighborhood of the appendix, one just below and extending behind the liver, and a third, containing about sixteen ounces of sero-purulent material, in the pelvis. The first two contained about four ounces each. The appendix was perforated. After excision of the appendix the abscess cavities were emptied and carefully cleansed with gauze wetted with 1:3,000 bichloride solution. The general peritoneal cavity was carefully dried, and gauze drainage strips led from the remote portions of the latter to the operation wound. The abscess cavities were also drained in the same manner.

After-treatment: Elevation of the head of the bed was kept up for five days. Strychnine and citrate of caffeine were given in moderate doses. There was gradual withdrawal of the drains. No vomiting took place. Fluids were allowed to the extent of the patient's desires in that respect. There was an enormous amount of fluid carried off from the peritoneal cavity by the drains. The patient recovered. No bacteriological examination was made.

Case VIII.—February 27, 1900; Methodist Episcopal Hospital. This was a case of post-operative diffuse septic peritonitis. The patient was operated upon for extensive ventral hernia resulting from an operative attempt to remove a myomatous uterus five years previously. Infection probably resulted from the use of an unusually thick strand of catgut (always difficult of sterilization) in ligating an exceptionally dense adhesion. Symptoms of peritonitis commenced within eight hours of the operation and increased with alarming rapidity until the entire peritoneal cavity was involved. The distribution and tenderness were extreme, the pulse 160 and feeble, and the peritonic facies well marked. The head of the bed was raised twelve inches from the horizontal; stimulants were administered (strychnine and caffeine), calomel was given, followed by salines; enemata of lac asafœtida were employed, and antistreptoccic serum was given. In spite of all these the alarming symptoms continued until the fourth day, when I accidentally learned that whenever the enemata were given the head of the bed had been lowered and the foot raised, to facilitate the retention of the latter. This had occurred quite frequently for the reason that saline enemata were likewise given in the intervals of giving the lac-asafœtida rectal injections. Upon investigation I found that this had been done about every three hours since the commencement of the treatment, the patient remaining in this position on an average of a quarter of an hour each time. The patient's condition at this time was alarming in the extreme. She lay with her eyes half opened and the globes rolled up; the abdomen was barrel-shaped; the pulse was almost imperceptible at the wrist, and the jactitation required the use of morphine. She had complained after each time of raising the foot of the bed of a burning sensation along the œsophagus; finally vomiting set in, and she rejected what was given by the mouth. The rectum had finally become intolerant, and her sufferings were extreme. It was at this time that the error was discovered and rectified. The head of the bed was permanently raised, and from this time improvement commenced. Flatus was expelled in copious quantities, and liquid movements of the bowels were obtained. The morphine was stopped, the ice coil being found to be sufficient to relieve the abdominal distress. By the second day following the persistent use of the elevated head and trunk posture her morale had so improved that she greeted me with a smile· the pulse had gradually fallen to 116 and was greatly improved in strength, and she was beyond the stage of anxiety. She finally recovered completely.

Case IX.—March 2, 1900; German Hospital. The patient, a young man aged sixteen years, was admitted with acute appendicitis of two days' standing. In spite of the fact that the attack was comparatively recent, a diffuse septic peritonitis was already under way. The abdomen was board-like and tympanitic, the peritonitic facies was present, and tenderness was extreme. Upon opening the abdomen sero-purulent fluid was found to be present, in which flakes of lymph were floating; the entire tract of the small intestine was intensely reddened, and fibrinous exudate was present. A long perforated appendix lying in the midst of the unprotected small intestines was brought out of the wound and removed. Eventration was then performed, the intestine being laid on the abdominal wall and well covered with gauze compresses, which were frequently wetted with warm saline solution. The immediate region from which the appendix had been removed was treated with two ounces of equal parts of peroxide of hydrogen and a saturated solution of bicarbonate of sodium. No attempt was made to disseminate this throughout the peritoneal cavity; and as much of this was removed as possible by flushing with saline solution, before proceeding further. The abdominal and pelvic cavities were then repeatedly washed out with large quantities of saline solution poured from a pitcher, at least twelve gallons being thus employed. The abdomen was then dried out, and the intestines were returned; a glass drain carrying a strip of iodoform gauze was placed in the pelvis and dressed separately from the abdominal wound, which was sutured down to the glass drain.

After-treatment: Elevated head and trunk position. Plenty of fluid was allowed, and no medication save small doses of strychnine and caffeine to bridge over the first shock of the operation, which was severe. Aspiration of the glass drainage tube was done every six hours. No vomiting occurred. Small doses of calomel (gr. $\frac{1}{5}$ every half-hour) were given until two grains had been taken. Normal peristalsis commenced within four hours, resulting in the expulsion of flatus, and liquid stools passed on the second day. Recovery followed. Bacteriological examination of cultures taken from remote portions of the peritoneal cavity showed infection.

Thus it will be seen that, of nine consecutive cases of diffuse septic peritonitis treated by the combined methods of elevated posture and drainage, all have resulted in recovery. I have not included among these several cases in which a spreading peritonitis existed about a focus of infection, as shown by decided redness of the coils of intestine in the neighborhood, and which were apparently arrested by the elevated head and trunk position. I may say, however, that in these cases the convalescence has been rapid, and the patient's condition has seemed to be more comfortable than is usual during the first few hours following the operation, mainly through the absence of vomiting. Because of this, however, and with the object of utilizing the elevated head and trunk posture as a prophylactic measure, I would strongly recommend the latter in all cases of abdominal section, even at the risk, if Sonnenburg's view of the mechanism of the production of phlebitis of the veins of the lower extremity following this operation should prove to be correct, of the occurrence of this complication.

For the purpose of comparison I have taken an equal number of cases of diffuse septic peritonitis occurring in my hospital services, the dates of which embrace a period of time corresponding as nearly as possible to that in which the foregoing were observed, and which were subjected to the same measures of treatment with the exception of the elevated head and trunk posture. Of these nine cases four patients recovered and five died. These cases were not taken consecutively, nor yet, on the other hand, were they selected cases. Had they been taken consecutively there would have been made a manifestly unfair record to any method of after-treatment, since the group would have included two cases which resulted fatally within twenty-four hours of the operation, and there would have been seven fatal cases out of nine, instead of five. Further investigation of the records does not increase the proportion of recoveries greatly, and, after making all due allowance for those cases which have ended fatally from conditions which destroyed the patient before any plan of after-treatment could have been effective, say within twenty-four hours of the operation, it has been practically impossible to lower the death rate but slightly below fifty per cent. It may likewise be stated, in passing, that the further back the records are searched the higher the mortality becomes.

The record of nine consecutive cases of diffuse septic peritonitis terminating in recovery is extraordinary, not to say startling, and no reasonable surgeon could expect such uniformly good results, even in groups of cases in which milder forms of infection are alone included, and from which patients living less than twenty-four hours are excluded. For it falls to the unhappy lot of every surgeon occasionally to encounter cases in which the deep brown or mahogany color of the intestine indicates a profoundly septic inflammation present in its muscular structures, which no means yet known is capable of successfully combating, and in which the patients even live beyond twenty-four hours. Yet in three cases in this group the infecting organism was identified, and in at least one of these the much-dreaded streptococcus was present. The following is a *résumé* of the nine cases treated without the addition of the postural feature of the first nine:

Case I.—January 26, 1898; Methodist Episcopal Hospital; acute appendicitis with perforation and diffuse septic peritonitis. Gauze drainage was used. The patient died. No bacteriological examination was made.

Case II.—January 27, 1898; Methodist Episcopal Hospital; acute salpingitis from infection by a uterine sound while under office treatment by the family physician. Diffuse septic peritonitis was present. Gauze drainage was used. Antistreptococcic serum, with saline infusion, was given. The patient recovered. No bacteriological examination was made.

Case III.—May 23, 1898; Methodist Episcopal Hospital; gangrenous appendicitis and diffuse septic peritonitis. Gauze drainage was used. Recovery took place. No bacteriological examination was made.

Case IV.—March 17, 1899; Methodist Episcopal Hospital; acute appendicitis and diffuse septic peritonitis. The abdomen was cleansed with decinormal salt solution. Flakes of lymph were removed with sterile gauze. Gauze strips for drainage were inserted in the general peritoneal cavity. Recovery took place. No bacteriological examination was made.

Case V.—April 8, 1899; Methodist Episcopal Hospital; acute appendicitis with perforation, and diffuse septic peritonitis. The abdominal cavity was flushed with decinormal saline solution. A glass drain was inserted in the pelvis, and iodoform-strip drains were passed from the abdominal peritoneum to the operation wound. The patient died. No bacteriological examination was made.

Case VI.—September 14, 1899; Brooklyn Hospital; ruptured ovarian cystoma with chocolate-colored contents. Diffuse septic peritonitis was present. Glass drains were inserted in the pelvis and gauze strips from the abdominal cavity to the operation wound. Saline infusion and antistreptococcic serum were used. The patient died. No bacteriological examination was made.

Case VI.—October 28, 1899; Methodist Episcopal Hospital; gangrenous appendicitis; diffuse septic peritonitis. The abdomen was dried out with sterile gauze. Glass drains were used in the pelvis. Recovery resulted. No bacteriological examination was made.

Case VIII.—November 2, 1899; Methodist Episcopal Hospital; acute appendicitis; diffuse septic peritonitis. Iodoform gauze drains were used in the abdominal cavity, and a glass drain in the pelvis. The patient died. No bacteriological examination was made.

The remaining case in this series possesses an especial interest in this connection for the reason that a novel and what may prove upon further trial a valuable addition to present methods was employed. I refer to the plan of securing drainage at the site of the root of the mesentery of the small intestine by a transversely placed rubber drainage tube through the latter, and repeated irrigations through this of large quantities of decinormal saline solution.[1]

Case IX.—February 22, 1900; German Hospital; the patient was admitted with diffuse septic peritonitis of appendicular origin. Operation revealed large quantities of sero-purulent material scattered throughout the general peritoneal cavity, with intestines matted together, pus, and with large patches of lymph. The appendix was violently inflamed, but not perforated. After removal of the appendix eventration was done, the intestines being removed loop by loop, and the coils carefully cleansed and the fibrinous patches removed by carefully wiping with sterile gauze. The intestines were then allowed to rest upon the abdominal wall and carefully covered with towels wrung out of warm salt solution. These were reinforced as to their heat from time to time, and shock from the disembowelling process was thus effectually guarded against. The peritoneal cavity was then flushed with several gallons of warm saline solution. A large rubber drainage tube was then passed through the root of the mesentery of the small intestine at about the middle of the abdominal cavity, and the ends were led out of openings made for the purpose in each flank in such a manner that the tube traversed the abdominal cavity in a transverse direction, being held down in the centre by passing through the mesentery. A similar tube was led from behind the liver and spleen, and two from the pelvic cavity, separate openings being made for the passage of these as directly as possible through the abdominal wall. The intestines were then returned to the abdominal cavity, and the operation wound was closed. Saline solution was passed through the upper tubes; this flowed freely from the lower ones.

After-treatment: Strychnine and citrate of caffeine were given for stimulation, with saline solution and whiskey by the rectum. Irrigation of peritoneal cavity through the tubes was done with a gallon of saline solution at 100° F. every six hours. With each irrigation gas passed freely per rectum. The distention subsided, vomiting ceased, and several spontaneous evacuations of fluid fæces took place. At the commencement of each irrigation séance, the fluid came through the lower tubes turbid, but before the gallon of irrigating fluid was exhausted it became clear. The general septic symptoms from which the patient was suffering when admitted, however, steadily progressed; she became delirious, and death took place from septicæmia thirty-six hours after the operation. No bacteriological examination was made.

I am aware that there are several sources of fallacy in estimating the value of conclusions drawn from the study of any method of treating diseases of bacterial

[1] Bode: Centralblatt für Chirurgie. No. 2, 1900.

origin, and the relation which the method bears to the results in any group of cases. Briefly, these fallacies have their origin in the relation which the following factors in the individual case bear to the result: (1) The pyogenic properties of the infecting agent; (2) the number of organisms present; (3) the susceptibility of the individual; (4) the inhibitory influences sometimes exerted by the peritoneal fluids upon micro-organisms. Elimination of the first of these, namely, the pyogenic properties of the infecting agent, is possible to a certain extent by proper bacteriological examination. The second, the number of organisms present, is capable of elimination only within certain limits, such, for instance, as the statement that the fluids were "swarming with bacteria," that the latter were present in "moderate quantities," or that "but few were found." But how shall we estimate the degree of susceptibility of the patients who perished, or the influences exerted by an immunity present in those who survived? To this individual factor of vital resistance are to be ascribed many of the discrepancies in results in groups of cases as they are presented, and which vitiate more than anything else statistics as they relate to different plans of treatment as advocated. This relates not only to the local susceptibility to infection and its spread, but to the general susceptibility as well. Yet the individual may possess an immunity to infection entirely independent of the factor of vital resistance. While it is true as a general proposition that those greatly depressed physically are more liable to perish from suddenly developed infectious processes, whether or not the latter is made possible by an operative procedure, it is likewise true that some individuals possess a decided immunity to infection entirely independent of any apparent high grade of physical condition on the one hand, while others exhibit a susceptibility altogether disproportionate to previously existing active or actually debilitating influences on the other hand.

A word as to the conditions present in the cases that have been denominated "diffuse septic peritonitis." It has been my happy lot to meet occasionally with conditions in which large quantities of opaque milky material, consisting of desquamated endothelial cells, leucocytes, and perhaps other cell forms floating about in a copiously transuded peritoneal fluid, have been found present in the general abdominal cavity, unaccompanied by any signs of peritonitis, the patient's recovery following as if such fluid had not been present. In these instances the fluid has been found as to its infective qualities to be insufficient to produce more than enough irritation to lead to an increased quantity of secretion of the peritoneum and to add some turbidity to the latter as described, the inhibitory or even destructive powers of the peritoneal fluids to the micro-organisms accounting for the sterility and consequent failure of infection. These have not been classed as cases of peritonitis. But when all peritoneal structures, both parietal and visceral, within sight from an ordinary abdominal section are observed to have exchanged their pearly pink color for a decided red or bluish-red, and particularly if this condition extends to the mesenteric folds of the small intestine, and patches of fibrin and pus cling to the surface of the latter, there can be no question as to the propriety of designating such a case as one of diffuse septic peritonitis.

If asked what, in my opinion, is the best general line of treatment for diffuse septic peritonitis as found to exist upon opening the peritoneal cavity, I might hesitate to express myself as being either for or against eventration or disembowelling for purposes of methodical cleansing; as well as the employment of peroxide of hydrogen solution, or the use of large quantities of decinormal saline solution for purposes of flushing out the peritoneal cavity. But there are two points upon which I would not hesitate to speak with confidence, namely, the employment of the elevated head and trunk position, and drainage of the pelvic cavity at least by means of properly placed and protected glass drains. I offer this as a method preferable to Clark's position, which is the exact reverse of this treatment, and I do it with the full knowledge of the alleged anatomical and physiological reasons advanced in support of the last-named method. Clark's position certainly does not empty the pelvic cavity of septic fluid, for the extent to which the patient must be inverted to accomplish this is incompatible with safety, or with his comfort to say the least, since practically he must be placed standing on his head. This was demonstrated by Dr. Eastman, the resident pathologist at the Brooklyn Hospital, in a series of experiments performed upon cadavers at my request. It is fortunate for those patients who have recovered under this treatment (and I might have said, in spite of this treatment) that this is true, for the reason that this would not only lead to the still further spread of septic fluids through the intestinal region of the peritoneal cavity, of itself a sufficiently dangerous area from the infective standpoint, but the septic fluids from the pelvis would finally reach the exceedingly dangerous infective area of the diaphragm, particularly the central tendinous portion of the latter, with its large lymph trunks and numerous stomata, which rapidly absorb blood, pus, and in fact fluid of whatever sort, with its contained bacteria and toxic débris, instead of being allowed to remain in or flow to the pelvic cavity, in the peritoneum of which are found but very few lymph trunks and stomata, and the capillary lymphatics of which soon become obstructed by lymph thrombi which prevent further spread of infectious material. For with the involvement of these lymph vessels the function of the latter is destroyed by the obstruction caused by thrombi, this constituting the method by which further invasion of peritoneum is prevented and the organism itself protected as well. Under these circumstances transference of the septic fluids from the most dangerous areas of the enormous lymph sac constituting the peritoneal cavity to its least dangerous region, namely, the pelvic portion thereof, and in case of operative attacks removing these from the latter by properly placed and protected means of drainage, constitute not only a rational but an imperatively demanded procedure.

OBSERVATIONS AND SUGGESTIONS CONCERNING HYPODERMOCLYSIS.

By ROBERT COLEMAN KEMP, M.D.,
NEW YORK,
CLINICAL ASSISTANT TO THE CHAIR OF SURGERY, NEW YORK POLYCLINIC MEDICAL SCHOOL.

THE Ilio-Lumbar Region for Hypodermoclysis: There have been numerous locations advocated for the subcutaneous injection of normal saline solution —such as beneath the breasts in females, in the chest, abdomen, thigh, axillary space, cellular tissue of the neck, back, etc. I would suggest, however, a region that seems especially advantageous—the space between the highest part of the crest of the ilium, and the lower border of the ribs—in effect the loin, but rather the outer margin of the lumbar region, and which for convenience I have denominated ilio-lumbar. It does not interfere with the dorsal posture, nor do movements of the limbs or neck, or thoracic or abdominal respiration, cause discomfort. It would seem, in fact, to be a point of very little motion. The illustration (Fig. 1) which was drawn from life by Mr. Thomas Nast, Jr., clearly demonstrates the method.

I am aware that some inject antitoxin into this region, and also that the lumbar site has been employed for hypodermoclysis, but I believe the puncture to be more dorsal in location. The lateral lumbar region would seem to be more advantageous, and I think it should be more frequently made the point of selection. It is not within the province of this article to describe the methods and indications for hypodermoclysis, but to direct attention to certain features, which I trust may prove to be of some interest. The normal (or, strictly speaking, decinormal) saline solution should be employed; the formula, roughly speaking, being in the proportion of ʒ i. of salt to Oi. of water. The solution should be sterile, also the needle, and the region to be punctured should be sterilized. The fountain syringe or the Davidson's syringe should also be sterilized. The character of the needle, the temperature of the fluid, and the regulation of the flow, together with the rapidity of absorption, I shall speak of later.

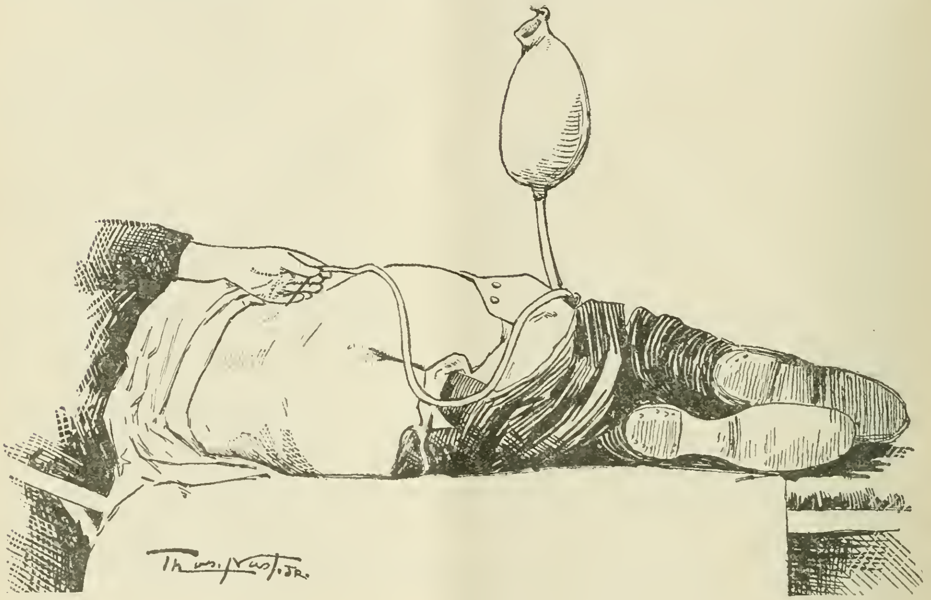

Fig. 1.

The Specific Effect on Renal Secretion Produced by Small Quantities of Normal Saline Solution: That there is a specific effect produced on renal secretion by even small quantities of normal saline solution, I believe it to be impossible to controvert. This holds true whether it is administered by infusion, hypodermoclysis, or enema. Thus Foster has demonstrated an immediate increase in the renal secretion, following an infusion with saline solution, even when an infusion of so small a quantity was given that no change in the general blood pressure occurred, and when in addition there was a complete severance of all the renal nerves, evidently a specific effect on the secreting cells of the kidney. Also in my own article, entitled "Physiological Experiments with Intestinal Irrigation," etc., published in the *New York Medical Journal*, January 29, 1898, experiments were reported regarding the effects of infusion and hypodermoclysis on renal secretion. An infusion of saline solution, to which a small amount of a weak solution of potassium ferrocyanide had been added, the total amount of fluid infused being less than ℥ ss., gave increased renal secretion, and at the same time the Prussian-blue reaction with chloride of iron, in one and one-half to two minutes. The urine drops were counted by means of the registering lever and kymograph to avoid possible error. The quantity infused was so small as to have no appreciable effect on the general circulation, no rise of tension being noted.

As regards hypodermoclysis, a subcutaneous injection of saline solution, to which a weak solution of potassium ferrocyanide had been added, caused increased renal secretion in three and one-half to four minutes, coincident with the Prussian-blue reaction to chloride of iron. This was the average length of time under normal conditions, and even when very small quantities were employed the increased renal secretion was noted as before.

By enema, I have noted clinically, as have others, the enormous increase of renal secretion following even very small enemata of normal saline solution. Thus in response to ℥ ix. of normal saline solution, given at half-hour intervals in divided doses—℥ iii. at each injection—there resulted forty ounces of urine within five hours from the first injection. Only ten ounces of bloody urine had been voided in the previous ten or eleven hours. The urine after the injections also was much less bloody in appearance. This is reported in "Transactions of the Association of American Physicians," vol. xiii., 1898, page 402, as a case of chronic infective endocarditis, a patient of Dr. William H. Thomson. I have noted frequently this enormous response to small enemata of normal saline solution—often three to five times the amount of urine being secreted, as compared with the quantity of saline injected. My own experience seems to show that the smaller quantities frequently repeated give better results than a few single large injections.

With hypodermoclysis, I have observed clinically, in a case of nephritis complicating diphtheria, an injection of ℥ iii.-iv. of normal saline solution caused a secretion of urine nearly five times the quantity, within four hours. The blood and albumin previously existing disappeared and the casts diminished in number. In another case, the patient, having albumin and casts in the urine, was operated on for tuberculous elbow-joint. Nitrous oxide and oxygen were administered for thirty-five minutes. A hypodermoclysis of ℥ vi. of normal saline solution was given before the anæsthetic was removed. The patient passed a third more urine in volume, the first twenty-four hours after operation, than in a corresponding time before it. The albumin disappeared and the casts lessened in number. Other illustrations could readily be given, and I have already called to your attention the physiological demonstration of the diuretic action of small quantities of normal saline solution by subcutaneous injection.

In the *Deutsches Archiv für klinische Medicin*, Lenhartz, in an article entitled "The Therapeutic Value of Saline Infusion in Acute Diseases," advocates frequently repeated injections, preferably subcutaneously and in moderate quantity, as promoting the excretion of injurious substances better than the employment of a very large volume of saline at each injection, given less frequently. My own view coincides with that of Lenhartz. I believe that the specific action of small quantities of normal saline solution on renal secretion has been clearly demonstrated, and advocate ℥ ii.– ℥ vi. injected frequently—every three or four hours—as a better diuretic and causing less strain on the kidneys than Oi. given three or four times daily.

Elimination, as I have demonstrated, begins in three and one-half to four minutes, and the smaller quantities of saline would soon be cast off. Hypodermoclysis is an excellent method to employ. The objection often urged as to a large quantity being necessary and hence painful, thus "falls to the ground," since small amounts are frequently more efficacious.

The Rapidity of Absorption is Modified by Existing Clinical Conditions: I have already briefly described the method by which I demonstrated that elimination of normal saline solution, given subcutaneously, begins in three and one-half to four minutes after the injection has been made. This is under normal conditions of the circulation. In the course of my experiments I noted that when normal saline solution was infused into the veins, elimination through the kidneys commenced in one and one-half to two minutes. If normal saline solution was given by enema or enteroclysis, the weak solution of potassium ferrocyanide again being added to it, the reaction appeared in the urine in twenty minutes. Dr. L. Bolton Bangs clinically has secured the reaction of potassium iodide in the urine in twenty minutes after its administration by enema.

Now though hypodermoclysis under normal conditions is in rapidity of entering the circulation next to infusion itself, yet under certain other clinical conditions the absorption is much delayed, and for practical use it is actually the least rapid in its action of the three methods. For a clearer understanding of the matter I will speak of certain, so to speak, "mixed" or rather "complex" effects of enteroclysis, since this can be employed as an adjunct to hypodermoclysis to hasten the absorption. With hot saline enteroclysis at 110°–120° F., I have the following effects:

First: An instantaneous marked increase in general arterial pressure—in other words, an immediate stimulation of the circulation and of a most marked character. This powerful effect does not occur when lower degrees of temperature are employed, but does so at from 110°–120° F.

Second: At about the end of ten minutes this stimulation seems to attain its highest degree, and the pressure remains stable. This was demonstrated in the experiments on "shock from hemorrhage," in the article to which I have referred.

Third: The increase of renal secretion as a result of saline enteroclysis at a high temperature (110°–120° F.) begins after about ten minutes' irrigation, coincident with this "height," so to speak, of general stimulation of the circulation.

Fourth: The increase of blood and body temperature also begins to manifest itself about this period (ten minutes after enteroclysis is begun).

Fifth: A second, and quite marked, increase of renal secretion is noted at the end of twenty minuets' enteroclysis, and this is coincident with the appearance of the Prussian-blue reaction, or due to absorption from the intestine.

Now, in uræmic conditions with a feeble circulation, or in shock, or any condition of such a character, the absorption of the lymphatics will also be nearly at a standstill; and even a small hypodermoclysis will take a considerable length of time to be absorbed. A subcutaneous injection, besides, has a certain degree of tension to overcome (caused by the pressure of the fluid itself), and also does not possess the advantage of stimulating by its heat, since a high degree of heat might be harmful in circumscribed cellular tissue under high tension, especially with the blood supply already enfeebled. In fact sloughing has occurred in the breasts from a too great (or too rapid) injection of saline solution.

Hot saline solution distributed over a large surface, as the peritoneum, or given by enteroclysis or enema, is an entirely different matter. There is here no resistant tension of high degree to be overcome; the fluid has a wide area of distribution for absorption, and, most important, there is an immediate reflex stimulation of the circulation itself from the heat, and hence in turn rapid lymphatic absorption.

In any clinical condition in which the general circulation is markedly impaired, hypodermoclysis is naturally a slower method than under other conditions; nevertheless it is of great value, for I find that, even so, absorption can be hastened by the addition of enteroclysis (at 110°–120° F.) while performing the hypodermoclysis, or even by a simple hot saline enema. I would advocate enteroclysis (continuous) at 110°–120° F. while giving the subcutaneous saline injection. Gentle peripheral massage during the injection also hastens absorption, and clinically I have noted excellent results secured by this combined method.

On the other hand, I shall mention a certain class of cases in which, though the rapidity of absorption is lessened, yet the results secured by hypodermoclysis would seem exactly to fulfil the indications. I refer to hypodermoclysis in hemorrhage from typhoid or gastric ulcers. This method seems to possess considerable value in these conditions. As I have just demonstrated, if the shock is severe, the method is somewhat slow, and more active measures are also required. In hemorrhage with moderate or even fairly severe collapse it may be of itself efficacious. It replaces the loss of blood, and also on account of entering the circulation indirectly through the lymphatic system is not so likely to start up hemorrhage by a more sudden and marked stimulation, as is infusion. The saline solution is claimed by some also to have certain hæmostatic qualities. I have frequently noted during the past seven summers in the Adirondacks, that some advocate giving small amounts of salt water by the mouth in cases of pulmonary hemorrhage, claiming this effect. Saline solution by the mouth I believe might be liable to cause vomiting and thus aggravate the bleeding, but I mention nevertheless the claims set forth. Overstimulation after pulmonary hemorrhage I have noted, however, with resulting secondary hemorrhage. I mention this danger, therefore, and believe hypodermoclysis to be safe and often efficacious, stimulating, so to speak, to the "safety line." Dr. William H. Thomson recently secured brilliant results in a case of hemorrhage from typhoid ulcer at Roosevelt Hospital, and I obtained an excellent result in a case of gastric ulcer with severe hemorrhage.

Hypodermoclysis in Poisoning: This method would certainly seem of value in cases of poisoning, especially by alkaloids, as it aids elimination through the kidneys and stimulates the heart and respiration. In mushroom poisoning this method has been employed, and with success, it is claimed. Infusion has also been used. In belladonna poisoning I would suggest its value. Since belladonna is markedly eliminated through the kidneys, hypodermoclysis in moderate amount and frequently repeated would be of service. Frequent catheterization of course should be employed. In opium poisoning, or in poisoning from other causes, it is worthy of trial.

Hypodermoclysis in Pleurisy with Effusion: I have found this of value in this condition, especially if insufficient diuresis is an etiological factor. In a case of this character it has been recently employed immediately following aspiration. An excellent result in double pleurisy with effusion due to renal insufficiency was secured on similar principle by hot enteroclysis in a case of Dr. William H. Thomson's. The effusion was absorbed without aspiration, in consequence of the diuresis produced. Renal insufficiency was the cause of the effusion. Hypodermoclysis could be employed in ascites or dropsy, or pulmonary œdema, etc. It should not be given in œdematous tissue.

Hypodermoclysis in entero-colitis in infants and children, etc., is of special value to replace the loss of fluid. The method has long been employed. Dr. R. H. M. Dawbarn in 1892, I believe, was the first so to use it in this country.

Hypodermoclysis as an Eliminative in Diphtheria following Antitoxin Injection: Experimentally we find that if a serum injection is followed later by a normal saline hypodermoclysis, renal congestion is much lessened. Thus in rabbits large doses of normal horse serum or antistreptococcus serum caused considerable renal congestion, as shown by pathological examination. The same doses of these serums if followed by saline hypodermoclysis caused markedly less congestion. Naturally hypodermoclysis should not immediately follow antitoxin injection, as it would probably eliminate the serum rapidly; but if given three or four hours later, it would aid in the elimination of the toxic products of the diphtheria, and also, it would seem to me, in the removal of any toxic products of the serum if such existed, or if the patient should be especially susceptible.

Hypodermoclysis in Nephritis Complicating Diphtheria; Enteroclysis also of Value: In this condition I recently secured a brilliant result in a patient of Dr. William H. Thomson. Renal complications appeared at once before antitoxin was administered—casts, albumin, a small amount of blood, and diminished secretion. Antitoxin (board of health), 4,500 units, was given: 1,500 the first dose, with no improvement; 3,000 five hours later. I believe frankly that a much larger dose should have been given on the first occasion. The renal condition still persisting four hours after the second injection, a hypodermoclysis of ℥ vi. of normal saline solution in the loin was given, followed at once by enteroclysis with normal saline solution at 115° F. for thirty minutes. Four hours later a second enteroclysis was given, and the urine immediately increased in quantity; in twenty-four hours only a few casts were found, and in forty-eight hours there was nothing abnormal. This was certainly most satisfactory.

Hypodermoclysis with Sodium Salicylate as a Diuretic in Uræmia, etc.: Dr. S. J. Meltzer has reported a most interesting case—a patient of Dr. Robert Abbe, of this city. The patient was suffering from uræmic suppression, and Dr. Meltzer, having noted the diuretic effect of sodium salicylate in his experimental researches, employed it clinically and with excellent results.

Hypodermoclysis in Preparation for Operation, or during Anæsthesia; Indications: One frequently sees patients brought to a hospital suffering from traumatism, such as a compound fracture, or even cases requiring minor amputations, in which there has been some loss of blood, and moderate stimulation may be necessary. I do not mean a condition of true shock, or a border-line case even, when infusion would be indicated. The customary procedures of heat, strychnine, whiskey, and hot rectal enema may have been employed. In such a case I advocate a preliminary saline hypodermoclysis of moderate size, ℥ vi.–viii., to replace the loss of blood, and to be given before operation. The somewhat slow absorption under such conditions could not overstimulate the heart and cause increased hemorrhage at operation, an objection that has been made to preliminary infusion in moderate collapse. I believe in just such cases hypodermoclysis to be an ideal method, to be followed on the operating-table by a hot saline infusion for the "prevention of shock," as first suggested by Dawbarn. In other words, a hypodermoclysis given as a "preventive" on the same principle with the "hot saline enema" added, may often render the "preventive infusion" unnecessary. I do not mean to minimize the value of "Dawbarn's method," since I thoroughly advocate it, having frequently seen its good results. I merely follow in his footsteps, believing that more attention should be paid even to slight hemorrhage before operation, and by replacing this loss of blood I aid in eliminating some danger.

In a case in which renal trouble is suspected, or is known to exist, a preliminary hypodermoclysis before operation might prove of value, ℥ iv., ℥ vi., or ℥ viii., and repeated again before the anæsthetic is removed. In the *New York Medical Journal*, December 2, 1899, in the conclusion of an article entitled "Further Experimental Researches on the Effect of Different Anæsthetics on the Kidneys," I cite a patient of Dr. William H. Thomson, upon whom I operated for tuberculous disease of the elbow-joint. Nitrous oxide and oxygen were selected as the anæsthetic, as the patient had a small amount of albumin in the urine and also granular casts. Dr. Bennett administered the anæsthetic for thirty-five minutes. A hypodermoclysis of ℥ vi. of normal saline solution was given in the ilio-lumbar region just before the removal of the anæsthetic. Though albumin was present in the urine the day before and the morning of the operation, even in the urine voided just before anæsthesia was begun, and also a considerable number of casts were found, the albumin was absent after operation; the casts diminished in number, and the urine increased twenty-three ounces, twenty-four hours after operation, over the amount voided twenty-four hours previously. The patient had at no time any difficulty whatever. This case is certainly suggestive at least, and as such is reported. If shock occurs during operation, or if it is feared from any cause, hypodermoclysis should be employed as an adjunct to other methods. As a post-operative procedure, in renal complications, sepsis, or shock, it is unquestionably a valuable adjunct.

A Single Attachment Converting an Aspirating or a Hypodermic Needle into a Needle for Hypodermoclysis.—This attachment consists merely of a small fitting, with a screw thread of a size suitable to screw into the average aspirating or hypodermic-needle. It has an enlargement adapted to fit snugly the rubber tube of a fountain syringe or Davidson's syringe. It is a simple and cheap device to save the trouble of tying into the tube the average needle, which is generally of small calibre even at its base. The attachment being metal can be boiled. An aspirating-needle of convenient size for hypodermoclysis can be purchased with it if so desired.

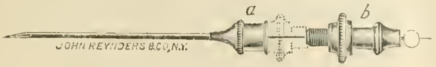

FIG. 2.

Regarding the needle, I may say that I have performed hypodermoclysis with successful results, even with the finest hypodermic needle and a fountain syringe. In such a case the fountain syringe had better be elevated six or seven feet, as the force exerted by the fine stream is slight, and extra back pressure is desirable. The fluid should flow freely from the needle as the puncture is being made. If the flow ceases, on account of the resistance to the small stream, pushing the needle in and then withdrawing it slightly or rotating it will generally start it again. This cessation of the flow is generally due to the small point of exit becoming clogged by the cellular tissue, and these movements will free it.[1]

There is a great loss of heat when the fine needle is employed, and the fluid in the fountain syringe should then be about as hot as the hand can bear comfortably, or about 110° F. It will reach the tissues at about the proper temperature. If the larger aspirating-needle is used, the fluid can be at 105° F., as even here there is considerable loss of heat.

The pain of the puncture can be avoided by freezing with ethyl chloride. Peripheral massage hastens absorption.

Doubtless many of these suggestions may prove to be already well known, yet I believe that merely by calling them to the attention of my professional brethren they may be more frequently employed with benefit than they have been heretofore.

NITROUS OXIDE AND ETHER ANÆSTHESIA.

BY H. W. CARTER, M.D.,

NEW YORK.

NITROUS oxide and ether anæsthesia, the nitrous oxide being used as a preliminary to ether, has been employed in England for a good many years, but until recently has been little used in this country. The method heretofore commonly employed in the United States was to use the gas through the American apparatus to the point of complete surgical narcosis, afterward using a separate inhaler to carry on the ether administration. This method, though a great improvement over the ordinary way of giving ether, is still imperfect, as a great deal of gas is required, and patients frequently partially recover from its effects before ether narcosis is established. The method usually employed in England, that of using a combined gas and ether inhaler, is far preferable, as the two agents are mixed after unconsciousness is produced, and the gas is not discontinued until satisfactory anæsthesia results. Owing to the expense of the English apparatus, however, and to the difficulty of replacing its parts when out of order, it has been little used here. Recently there has been placed upon the market an apparatus of American make which is the equal in every detail of the English (Clover-Hewitt) apparatus, and in some respects is superior. The apparatus was devised by Dr. Thomas L. Bennett of this city, and is manufactured by Messrs. G. Tiemann & Co.

Nitrous oxide is a colorless gas having a faint but pleasant odor and a sweetish taste. Four gallons weigh one ounce. It is liquefied by a pressure of fifty atmospheres at a temperature of 44.6° F. It is now generally sold in liquid form, being put up in strong portable steel cylinders.

When nitrous oxide is inhaled, the patient experiences a pleasant sensation of warmth and numbness, and has an irresistible desire to breathe quicker and more deeply. The pulse under the finger is accelerated and feels full and strong. After a few seconds consciousness is lost, the pupils begin to dilate, and the pulse appears to be lessened in tension. The respirations are somewhat slower, but are still regular and increased both in number and depth over the normal. At this stage the features begin to lose their normal color, and slight twitching of the extremities may be observed. This duskiness of countenance is most pronounced in full-blooded or extremely florid subjects, while anæmic or sallow persons show little change. If the inhalation is continued a few seconds longer without the admission of air, the pupils usually become widely dilated, the pulse is rapid and weak, and the respiration slow, stertorous, or irregular in character. The features grow darker, tonic spasms of the thoracic and abdominal muscles or the muscles of the extremities occur and may be pronounced or slight, and the conjunctival reflex is abolished. Anæsthesia is now complete, and air must be admitted.

In nitrous oxide and ether anæsthesia it is not necessary to push the gas to the point of stertor, jactitation, etc.

In this short paper it is impossible to give a full description of Dr. Bennett's apparatus (*vide* page 524). It consists of a face piece, ether chamber, gas inhaler, and a gas and ether bag. The ether chamber is composed of an inner cylinder which is made to revolve within an outer one. Running through the inner cylinder is a large tube which permits the passage of air or gas through the ether chamber. Around this tube is placed a removable wire cage (for gauze or sponge), leaving abundant space between it and the chamber wall for the free circulation of air or gas. The gas inhaler is much smaller than the ether chamber, and is so constructed that when the inner cylinder is rotated breathing may be made to take place through valves, or valve action may be suspended and to-and-fro breathing employed. The apparatus can be used separately as an ether or gas inhaler, or may be combined.

Before beginning the administration of an anæsthetic it is necessary to observe a few precautions which will bear repeating here. The administration should not be made after a full meal. If it is absolutely necessary to give an anæsthetic within six hours after taking solid food, the stomach should be thoroughly washed out before beginning. The bowels should be thoroughly evacuated the night before operation, and if necessary followed by an enema the next morning. In my experience the salines act best for this purpose, and if the liver is inactive may be preceded by small doses of calomel. The salines, particularly the magnesium sulphate, act quickly, clear out the intestinal tract thoroughly, and leave its secretions in a healthy condition.

The vegetable cathartics cause more or less violent and irregular peristalsis, which keeps the patient awake, and they usually leave the intestinal tract in an irritable condition. I have frequently recognized in the dark vomited material following an afternoon operation the compound licorice powder taken the night before, and have observed that patients who had taken a saline did not vomit to the same extent and suffered very little from intestinal disturbances afterward. Solid food of any kind should not be permitted for twelve hours previous to operation. Some light liquid diet may be given a few hours before the administration, and I have found that patients who have taken such are less liable to suffer from nausea than those whose stomachs are entirely empty for several hours before the operation.

---

[1] This attachment can be converted into an improvised antitoxin syringe, by connecting a small glass syringe with a sharp point by means of a short piece of tubing. The antitoxin can be measured with the barrel of the hypodermic syringe, before taking it up with the glass syringe. The improvised syringe can be easily boiled.

The heart, lungs, and arteries should be carefully examined and the urine tested for albumin before and after administration. Inquiry should be made with reference to false teeth, and if present they should be removed. The patient should be warmly clothed in loose garments, and all constricting bands about the waist, or anything that might in any way impede or embarrass respiration, should be removed.

The room in which the operation takes place should be warm and free from draughts to avoid chilling of the body. Weak or emaciated patients or patients having a weak heart should be given gr. $\frac{1}{30}$ of the sulphate of strychnine three times daily for several days previous to operation. The importance of this point cannot be too much emphasized, as it strengthens the heart and circulation, stimulates the respiration and nervous system, and fortifies the patient against shock. When this course has not been pursued gr. $\frac{1}{30}$ should be given hypodermatically half an hour before commencing the administration.

If the patient is in good general condition, I do not think it advisable to use previous stimulation.

In extremely nervous patients, morphine in small doses administered subcutaneously fifteen minutes before beginning the administration of an anæsthetic sometimes proves a very valuable drug, inasmuch as it quiets the nerves, stimulates the heart, relieves the pain after operation, and lessens the dangers of shock. Owing to the fact, however, that some patients have an idiosyncrasy against morphine, it is best to inquire if it has ever been taken or any unpleasant effect from its use experienced. On two or three occasions when I have anæsthetized the same patient more than one time, I have observed that the vomiting after ether was much more persistent when morphine had been administered, and inquiry elicited the information that it had always made the patient sick. On account of the marked similarity between alcohol and ether, whiskey or brandy should not be given immediately before etherization.

When administered in the ordinary way it is not always absorbed in time to produce the desired effect; it sometimes increases the excitement of the patient and oftentimes retards rather than accelerates narcosis. When the stimulating effect of alcohol is desired it is best to administer it subcutaneously. No one should undertake the administration of an anæsthetic without first being prepared to meet any emergency. All instruments and remedies necessary for resuscitation or in case of accident should be within reach. Such remedies as amyl nitrite, spirit of ammonia, and oxygen for immediate inhalation should be at hand, as well as prepared hypodermics of strychnine, digitalis, whiskey, atropine, camphor, etc.

A suitable mouth gag, tongue forceps, and sponge-holder should be within reach. Apparatus for the transfusion or rectal injection of saline solution should be available, and also instruments for tracheotomy. While these extreme measures will rarely be necessary, still if a patient should die on the table the anæsthetist would hardly be excused for not being prepared to meet any emergency. All these things, together with the inhaler, gas cylinder, and ether supply, can be neatly packed into an eighteen-inch dress-suit case.

A careful record should be taken of every case anæsthetized.

The Administration.—The face-piece, cushion, and ether chamber being sterilized and the whole apparatus carefully inspected to see that the valves, etc., are in perfect working order, the wire cage within the ether chamber is packed with sterilized absorbent gauze, and from one-half an ounce to an ounce of ether poured in. The index on the ether chamber is turned to "air," and the cushion moderately inflated to secure perfect adaptation to the face. The gas inhaler is attached to the chimney of the ether chamber. The aperture on the gas inhaler is left open, the air tap on the face-piece closed.

The gas bag, all air being first pressed out, is filled and attached to the gas inhaler.

The cushion is now gently but firmly adapted to the patient's face, the patient being informed that he is breathing nothing but pure air, and instructed to take long and deep breaths. As soon as he has become accustomed to the apparatus and his fears are somewhat allayed, the tap of the gas bag is quietly closed. The patient inhales gas through the inspiratory valve and exhales a part of it mixed with the residual air of the lungs through the expiratory valve. When the bag has become about two-thirds emptied, the aperture of the gas inhaler is closed by turning the thumb-screw, and valve action is suspended. The patient now breathes back and forth into the bag. As soon as unconsciousness takes place, the index on the ether chamber should be immediately turned to a little beyond the mark between "air" and "ether," admitting a small quantity of ether fumes. The patient is allowed to take two or three inspirations, when the index is moved a little farther along, permitting a mixture of gas and ether to be inhaled. The respiration and countenance at this stage should be carefully watched, and if any signs of asphyxia develop, the tap of the gas bag should be opened and a single inspiration of air allowed. The index should be slowly moved forward, pausing long enough between each advance for the larynx to become accustomed to the increased strength of the ether vapor, and admitting air as necessary until the ether is fully on. The patient continues to breathe a mixture of gas, ether vapor, and a small quantity of the residual air of the lungs to and fro into the gas bag, these passing through the gas inhaler and around the wire cage of the ether chamber to the face-piece.

When anæsthesia is completed, which usually takes place in from two to three minutes, the gas inhaler and bag should be detached from the ether chamber, and the ether bag attached.

Ether may now be added through the revolving disc on the side of the ether chamber opposite the thumb-screw or through the face-piece, and the admission of air regulated as desired.

By leaving the tap of the ether bag open, the apparatus can be used practically as an open inhaler, or by closing it to-and-fro breathing can be employed, air being admitted through the tap on the face-piece.

By detaching the bag, the inhaler fulfils every requirement of an open cone.

The administration is now continued in the ordinary way.

The Guides to Proper Anæsthesia.—Of all the guides to the proper depth of anæsthesia, the respiration is the most important, and in the respiration lie the chief dangers of etherization.

I think all will agree with me that the principal troubles with this function arise during the first stage of narcosis, and are due to the strong ether vapor coming in contact with the upper air passages, causing clinching of the teeth, attempts at swallowing, coughing, or vomiting, closure of the glottis, profuse secretion of mucus, and spasm of the chest muscles, which may embarrass or arrest respiration. These symptoms, though usually only troublesome, do sometimes occasion great alarm, and have necessitated the performance of artificial respiration and even tracheotomy. Thanks to nitrous oxide they are now eliminated, and the patient enters directly into the second stage of ether narcosis.

When ether is properly administered, the respiration as a rule is regular and distinctly audible, slightly stertorous in character, and somewhat accelerated, a puffing movement of the lips and cheeks with each expiration being frequently observed. However, each case is a law unto itself, and by studying the effect of more or less ether upon the rate, depth, and audibility of breathing, a fixed standard can soon be obtained. If the breathing becomes inaudible or loses its stertor more ether is required, and this sign will soon be corroborated by a slight cough or a swallowing movement. If the respiration becomes deeply stertorous or embarrassed it is indicative of paralysis of the muscles of the soft palate, and the ether should be diminished.

This condition should not be confounded with the loud snoring noise sometimes made by patients under ether.

While the chief dangers to respiration arise during the first stage, it must not be forgotten that an abundant secretion of mucus at any stage may partially cut off the air supply, causing marked cyanosis, and that too great a restriction of oxygen may cause sudden respiratory failure.

Great care must be taken to keep the mouth and throat clear and the air passages open by frequently using the sponge-holder, lowering and turning the head to one side, and extending the neck well upon the shoulders, at the same time lifting the chin. This manœuvre raises the base of the tongue from over the glottis, causes the mucus to run out, allows free inspiration, and opens the air way.

I have notes of the following case: Mr. H——, aged forty-eight years; general condition poor; very nervous temperament; temperature, 99° F.; pulse, 88; respiration, heart, and blood-vessels normal; urine contains some pus and slight trace of albumin. He had taken gas before. Ten minutes after operation began anæsthesia was progressing favorably, though there was slight cyanosis about the ears. The patient was getting plenty of air and there was little or no secretion of mucus. The respiration was good, the pulse full and strong. The air passages were open, the muscles relaxed. The blood was of good color. Suddenly the respiration ceased; the pulse continued full and strong. The ether was withdrawn, artificial respiration performed, and oxygen administered; at the same time hypodermatic injections of atropine and strychnine were given. The operation was continued. In a few minutes the respiration became fairly satisfactory, but as soon as the ether was resumed it suddenly stopped. Artificial respiration was again resorted to, and the operation finished under chloroform. This was evidently a case of idiosyncrasy for ether, the drug causing paralysis of the respiratory centre, as the patient continued to breathe under small quantities of chloroform. After the operation the patient had no further trouble and made an uneventful recovery.

Soon after the administration of ether is begun the arterial pressure rises and the peripheral blood-vessels dilate, leading to flushing of the face and profuse diaphoresis. As long as the skin remains flushed or heightened in color no danger need be feared on account of the circulation, but should it assume a marked degree of pallor or lividity, there is danger of heart failure, and cardiac stimulants should be administered.

The Reflexes.—By placing the finger on the throat the occurrence of any swallowing is easily recognized. This is often the first indication of returning reflex activity, and is soon followed by coughing or vomiting if the ether is not increased. While the conjunctival reflex is a very valuable one, it is a bad practice to touch the cornea, on account of a possible resulting conjunctivitis. If it becomes sufficiently strong to require an increase of ether, it will usually respond to lifting of the upper lid.

The pupil is of little value as a reflex until anæsthesia is fully established. By noting the effect of more or less ether, the proper size for surgical narcosis is easily learned. If the anæsthetic is used too lightly the pupil will dilate; also if it is used too freely it will dilate. That is, there may be two causes of dilatation, the first of reflex origin, the second of profound etherization. It is sometimes difficult to tell just what a dilated pupil means. In such a case the other guides should be consulted, but if a little more ether is used, the pupil will either contract or dilate still further. If it contracts it shows that the dilatation was of reflex origin; if it dilates still further, that the ether has been pushed too far and should be decreased. It is easily seen that the pupil may dilate reflexly from some operative procedure, and that an increase of ether may at first cause it to contract and a little later to dilate again, but this second dilatation is the dilatation of profound anæsthesia and shows that the increase has been carried too far. As a rule the pupil grows smaller as the administration is continued, and occasionally remains contracted throughout a long operation.

It should be remembered that the restriction of air always tends to make the pupil dilate. No one guide or reflex can always be entirely relied upon, but they are all of value for corroborating one another, and cases sometimes arise in which the corroborative evidence of all must be taken into consideration in determining the exact depth of anæsthesia. In conclusion I will briefly state the advantages of this method, viz., economy, safety, saving of time to the operator, and elimination of the disagreeable features of ether inhalation. As the quantity of ether inhaled is comparatively small, patients recover more promptly, nausea and vomiting are of much shorter duration, and intestinal after-disturbances are reduced to the minimum.

In ordinary ether administration it often takes more ether to induce narcosis than is afterward required for a long operation. The almost absolute safety of gas, its pleasantness and rapidity of action make it a most welcome agent to any patient who is to undergo a surgical operation. Indeed, the small quantity of nitrous oxide actually required is sometimes surprising, one bagful (about two gallons) being sufficient for any case, and I have succeeded in inducing perfect anæsthesia, without the least discomfort to the patient, with only half a bag.

The quantity of ether required in ordinary cases is less than one-half, and oftentimes one-third, of that consumed when the open cone is used, a single 250-gm. tin sometimes sufficing for three lengthy operations.

In kidney or lung affections in which the condition of the heart forbids the use of chloroform this economy of ether is certainly a very great advantage. The following case serves to illustrate this point:

Mr. B——, aged seventy-four years, three weeks previous to operation had marked ascites with œdema of the lungs and general anasarca of the lower extremities, face, etc. At this time he was passing nine ounces of urine in twenty-four hours, which contained about fifteen per cent. of albumin. The heart was slow and very weak, but its sounds were normal. Under treatment these symptoms practically disappeared. At the time of operation the patient was passing forty-five ounces of urine daily, which contained a slight trace of albumin, but on account of the weakness of the heart it was decided to administer ether instead of chloroform. Anæsthesia was induced with gas, and the patient kept under ether one hour and a half. The urine was examined every day for a week after without any increase of albumin being noted, and the patient continued to pass a satisfactory quantity.

Finally, I would advise any one who may use this method to reassure the patient by explaining the pleasant effects of gas, its safety and rapidity of action, and the fact that none of the disagreeable sensations of ether inhalation will be experienced.

It is also very important that the administration should take place in a quiet room, and that nothing, such as loud talking, should occur to distract the patient's attention. If the patient's confidence in the administrator and the agent he employs is thus won, and these precautions are strictly observed, the slightest difficulty with the administration will rarely ever be experienced.

148 East Thirty-fifth Street.

CHRONIC VERTEBRAL RHEUMATISM (RHEUMATIC SPONDYLITIS) AND ITS PSEUDO-NEURALGIC FORM.[1]

By H. FORESTIER, M.D.,
AIX-LES-BAINS, FRANCE.

The question of chronic spondylitis is just now before the medical profession. Lately two important papers were published on this question in this country: one by Dr. Zenner, of Cincinnati,[2] the other by Dr. Dana, of this city,[3] and at the same time the New York Neurological Society, in November, 1899, had an important discussion of this subject in which Drs. Sachs, Gibney, Dana, Collins, and Peterson took part. The variety of spondylitis which they have spoken of is the one characterized by ankylosis of the spine, presenting two distinct types, one described by Bechterew, the other by Marie and Strümpell.

Cases of chronic spondylitis which I have observed in Aix-les-Bains, and which I am going to describe as a pseudo-neuralgic form of chronic vertebral rheumatism, are somewhat different, having the following clinical characteristics:

1. Temporary rigidity of the vertebral column, without any ankylosis, from muscular contraction, giving the patient a peculiar stiff gait; these symptoms depend upon the pain which the patient feels when he moves the trunk. 2. Predominant pseudo-neuralgic symptoms, nerve-roots symptoms; intercostal girdle pains; pains radiating from the back through the lower limbs, simulating in some instances either tabes or pachymeningitis spinalis externa, or even Pott's disease. 3. Coincidence of arthritis involving some peripheral joint, showing there is a rheumatic process. 4. Curability under such treatment as the Aix-les-Bains douche-massage, the recovery showing that the pathological process may be considered as rheumatic.

As far as I know, but little has been written on such cases. Classical text-books give but a short account of vertebral rheumatism. They describe the usual varieties, torticollis, lumbago, and simply mention the fact that pseudo-neuralgic symptoms may occasionally occur in some cases.

Papers published on the subject of spondylitis or chronic stiffness of the vertebral column (as reported by Dr. Zenner and Dr. Dana) and on the subject of articular lumbago[1] do not record cases presenting the clinical features of those I am about to describe. I must mention that I have published a first account of them at the International Congress of Hydrology at Liège, October, 1899.

Case I.—Mr. M——, priest, aged forty-one years; family history negative. Personal history: He was generally healthy up to the age of thirty-five years. Since then he has become stout through rich food and lack of exercise. Three years ago he had pains in the left lower limb and in the neck. The present illness began in March, 1897. At that time he began to complain of pain in the region of the right hip, called sciatica, and accompanied later on with swelling of the left lower limb, suggesting the possibility of phlebitis. Shortly after pains appeared in the chest (girdle pains) radiating through the lower limbs; and in the mean time there was rigidity of the posture and gait. His physician thought there might be disease of the spinal cord, but after a while, the patient's condition being no worse, he sent him to Aix-les-Bains. Present state, May, 1897: He is a man of medium height and well-built. At first glance the attitude strikes one: the patient walks rather slowly, the trunk keeping rigid. He complains of an almost continuous pain in the back (girdle pain), increased by coughing and sneezing, and radiating through the thighs, with shooting pains. Movements of the trunk, lateral or antero-posterior, as getting into or out of the bed, cause marked pain. He feels more comfortable when seated than when lying down. He cannot straighten the body. Movements of the neck are free from pains. Examination shows that the vertebral column is rather straight, the normal lumbar concavity being absent, and that there is no real impairment of motion, the rigidity being simply muscular in consequence of the pain. There is tenderness on pressure along the spine from the fourth dorsal vertebra to the sacrum, and over the sciatic nerve, but there is no tenderness over the loins. The knee jerk is exaggerated. Signs of articular rheumatism are present; the right foot is swollen and painful, all the joints being involved. There is no sign of a previous phlebitis. The knees are stiff. There is cardiac arrhythmia; the sounds are not very distinct; the heart is fatty. The urine is normal.

Thermal treatment: The patient was put under the general douche-massage, applied by two masseurs especially to the back, the patient being in a reclined posture; the temperature of the water was 85°-90° F.; duration ten to twelve minutes. Twenty douches-massages were taken with an interruption every four days. There was an immediate improvement which three months after the treatment was greater and continued. When I saw the patient in 1898 he was perfectly well.

Case II.—Mr. M——, aged forty-eight years. Family history was negative. Personal history: At the age of thirteen years he had acute articular rheumatism with several relapses. He had thermal treatment in Aix in 1888. Since then he has been healthy for some years. His present illness began in November, 1897; he began to complain of pains in the lower limbs, like sciatica, alternately on the right and left side, with intercostal and girdle pains. These symptoms getting worse, his doctor thought of a disease of the spinal cord, and made several times a Paquelin cauterization along the spine, which gave a pretty satisfactory result. Later on, giving up the idea of a nervous disease, he sent the patient to me in Aix-les-Bains. Present state, June, 1898: He is a tall and well-built man. His general condition is not satisfactory. He is in a state of nervous excitement (confesses he takes brandy pretty often). His posture and gait are stiff; he cannot straighten the body, and walks, keeping the trunk immobile, with his feet far apart. He complains of intercostal and girdle pains. When he has walked any distance he feels weak and has shooting pains in the lower limbs. In the early morning he has a backache. Examination shows in the upper part of the spine a slightly rounded curvature; slight lumbar scoliosis. He has tenderness over the spines of the lumbar region and over the lower intercostal spaces, and over the sciatic nerve also. Pressure upon the head produces pain in the lumbar region. The movements of the trunk are difficult and painful. The patient can hardly lie flat on his stomach and turn in bed. The knee jerks are brisk.

Thermal treatment: Twenty-five general douches-massages were given. At the end of the treatment the patient felt a very distinct improvement, which remained for two months afterward. In September he came back to Aix to have a second course of treatment. At that time I found the tenderness over the spine had disappeared. The recovery was almost complete. When I saw the patient last summer he was all right.

Case III.—Miss P——, aged twenty-five years, milliner; family history negative. Personal history: She has been generally healthy, although she was not of a strong constitution. In December, 1894, she took a walk of about twenty miles in the snow, after which she was seized with an acute articular rheumatism. She was laid up almost fourteen months, partly in the General Hospital of Lyons. Recovery was tedious in consequence of arthritis of the knees and ankles. She was sent to me in Aix-les-Bains. Present state, September, 1895: The patient is of medium height and thin body. The posture and gait are stiff; she walks rather slowly, keeping the trunk immobile. She complains chiefly, after walking, of pains in the back (girdle pains) irradiating through the lower limbs. She has a limp on the right side. Examination shows wasting and flaccidity of the muscles of the limbs; tenderness along the entire spine with the exception of the upper thoracic region; tenderness over the sciatic nerve. Movements of the trunk are painful and accordingly diminished. At the neck there is tenderness on pressure over the lateral processes, causing radiating pains through the upper limbs. The knee jerks are exaggerated. The general condition is pretty good, but she has chronic catarrhal colitis.

Treatment: The patient took a course of twenty general douches-massages.

September 29th: Improvement was shown. The pains were relieved; no limp was visible.

In the course of the winter of 1895–96 the pains recurred in the limbs and trunk. She was admitted to the General Hospital in Lyons, where for a time Professor Teissier, impressed by the neuralgic symptoms, thought of a possible pachymeningitis spinalis externa. After an accurate observation the case was considered one of rheumatism, and the patient was sent again to Aix-les-Bains. When I saw her in the season of 1896 her condition was the same as the year before, the neuralgic symptoms being more marked. She took a thermal treatment of about twenty general douches-massages and was improved. The improvement has been continuous since then. In 1897 the patient, having recovered, went back to work. When I saw her in 1898 she was perfectly well, except that the catarrhal colitis still existed in a slight degree.

Case IV.—Mr. C——, aged thirty-nine years, commercial traveller. Family history negative. He has been generally healthy, but he has taken little exercise and lived high. In 1886 he had his first attack of regular articular gout, and since then has had further attacks every year. For four years (namely, since 1888) he has suffered from girdle pains and pain in the right lower limb (sciatica), and has become stiff. Being afraid that he was affected with a disease of the spinal cord he consulted Charcot, who sent him to me in Aix-les-Bains, diagnosis being reserved. Present state, May, 1891: He is a tall and well-built man. Posture and gait are stiff. He takes short steps with his feet far apart, keeping the trunk immobilized because of the pain on attempted movement. The patient complains of intercostal and girdle pains, of pain in the right hip region increased by coughing. In the early morning he usually feels a backache. Examination: The normal lumbar concavity is absent; the patient cannot straighten the body; slight dorsal scoliosis is present. There is tenderness on pressure over the second, third, and fourth lumbar vertebræ. Pressure upon the head and shoulders produces girdle pains. Partial mobility of the spine exists, but the movements are painful. The patient suffers when attempting any act which necessitates a movement of the trunk, as picking up something from the floor, or getting in and out of the bed. The knee jerks are rather weak. A gouty swelling remains in both feet.

Thermal treatment: Twenty-two general douches-massages with two masseurs, applied especially to the back in reclined posture.

June 21st: The patient is very much improved; he can pick up things from the floor; he moves the trunk well. When I saw the patient one year after he was much better: he had had no further attack of gout, no pains; the mobility of the spine was greatly restored. Since then the patient has come every year to Aix and is getting on very well.

Case V.—Mr. C——, aged thirty-five years, manufacturer. Family history is negative. Personal history: He has been generally healthy, but has been accustomed to a sedentary life and excesses at table. In March, 1894, he suffered from subacute arthritis in the wrists, shoulders, and knees, which was probably subacute rheumatism. He received thermal treatment at Aachen. In November, 1895, he began to complain of intercostal pains, increased by coughing, together with pain and stiffness in the neck and in the large joints. He was sent to me in Aix. Present state, June, 1896: He is a tall and well-built man. Posture and gait are stiff. When he walks he keeps the trunk and neck immobile, the head being a little pushed forward. He complains of intercostal and girdle pains, increased by coughing. Examination shows the upper half of the spine to be slightly bent and pushed forward. The lower half is rather straight because of the absence of the normal lumbar concavity. There is tenderness on pressure along the entire spine, most marked in the middle dorsal region; there is also tenderness on pressure over the lateral processes of the cervical vertebræ. Mobility of the spine exists, but the movements are painful. The cervical spine is stiff; flexion of the head is diminished. There is a tendency to a more advanced stiffness than in the former cases. Shoulders, elbows, wrists, knees, and ankles all are more or less the seat of a rheumatic process as marked by swelling and pain.

Thermal treatment: A course of twenty-five general douches-massages was taken within thirty days. At the end of the thermal treatment the patient was improved; he had less stiffness in the neck, fewer pains, and the rheumatic arthritis had resolved. Improvement has continued since then. Later on the patient was entirely cured, the neck remaining a little stiff.

Summary of Cases.—All these cases present a peculiar clinical aspect. The posture and gait of the patients strike one. The patient stands up, slightly bent forward, and cannot straighten the body. He walks slowly, with the feet far apart in some cases, keeping the trunk immobile. The neck not being involved, the patient is not so stiff as in the Bechterew type.

The subjective symptoms are very characteristic; there are pseudo-neuralgic symptoms predominant from the onset of the disease. These nerve-roots symptoms are very like the one reported by Drs. Dana and Zenner, in ankylosing spondylitis. Patients complain of various pains irradiating from the back: intercostal pains, girdle pains, radiating pains through the lower limbs, sometimes the upper limbs (Case III.). These radiating pains may have the character of shooting pains (Case IV.). These pains are increased on attempted movements of the trunk when walking, or when coughing and sneezing. A very peculiar feature is the backache occurring in the early morning or when the patient has been lying down for some hours.

I must notice here that there are no more marked sensory troubles, no paræsthesia, no trophic changes, no muscular atrophy as it occurs in cases of the Bechterew type. There may be simply a certain degree of wasting and flaccidity as in Cases I. and III.

The knee jerks are exaggerated, as a rule, with the exception of one case. There may be ankle clonus as in a case recorded here.

Examination shows: (1) No deformity of the spine, but either the absence of the normal lumbar curvature or a slightly rounded posterior curvature of the upper half of the spine (Cases II., IV.). The lower half is rather straight. (2) Mobility of the spine exists when the patient moves the trunk in spite of the pain. Of course there is a certain stiffness because of the immobility. But there is no real ankylosis as in the Bechterew type. The trunk is immobilized because of the pain which even slight movement causes. (3) Tenderness on pressure over the spine and lateral processes (Case III.) sometimes is deep-seated. It is not simply hyperæsthesia of the skin as in spinal irritation. Tenderness exists too along the lower intercostal spaces (Case II.), and over the upper sciatic nerve, as in all cases. As it appears from the topography of tenderness the whole spine as a rule is not involved. The dorso-lumbar column is mostly affected, the neck being rather seldom involved (Case V.). Besides the tenderness over the spine there may be pain in the back when pressure is made upon the head or shoulders (Cases III., IV.). There is no tenderness in the loins in any case, which is not in favor of a primary muscular trouble (myositis).

The etiology of the cases is marked by a rheumatic history in all patients; sometimes gout is in question, as in Case IV. In Case I. there was slight chronic rheumatism in one foot, and sciatica probably. But the other patients have been affected with more or less severe acute or subacute articular rheumatism.

A clinical feature which differentiates the pseudoneuralgic form from the ankylosing one of vertebral rheumatism is that the former is curable. All these patients have been more or less entirely cured; I mean they have recovered for a time at least, a further relapse being possible.

Myxœdema.—Nicola de Dominicis considers this affection to be a complex of lesions of every part and every system of the organism, with multiform manifestations. It may be considered as a special type of diabetes, the primary lesion being in the thyroid gland, with secondary alterations of the nerve centres and of the various tissues of the organism. We may call it thyroid diabetes just as we speak of pancreatic diabetes. The injection of thyroid extract may be of value before incurable lesions of vital organs have been formed. —*Gazzetta Internazionale di Medicina Practica*, February 28, 1900.

TREATMENT OF SUPERFICIAL WOUNDS WITHOUT SUTURES.

By JOHN F. W. WHITBECK, M.D.,
ROCHESTER, N. Y.

To close superficial wounds many of us have used hair braiding for the scalp, and compresses, adhesive strips, bandages, collodion, and other available means, but sutures have been so universally employed that most physicians think they are indispensable. The question generally is not why, how, or when to dispense with sutures, but what suture material to use and how to apply it.

A comparison of different materials and methods extended over many years of observation has convinced me that absorbent cotton and collodion combined will secure prompt and good union of superficial incised and lacerated wounds. To obtain good union, however, it is important to observe a few first principles.

We must have an aseptic wound and a clean skin. The skin can be cleansed with soap and hot water, close shaving, and alcohol. Asepsis of wound and skin is then made sure by a careful wiping with dossils of absorbent cotton which have been soaked a few minutes in a 1 : 500 solution of bichloride of mercury. As soon as the parts are dry enough for the collodion to adhere, the edges of the wound are brought together and secured by cotton and collodion alone, or with the help of narrow strips of isinglass plaster moistened with the bichloride solution, or by similar strips of muslin or linen painted over with a thin coat of fresh flexible collodion. The thinnest possible layer (a mere layer of fibres) of dry, aseptic absorbent cotton is to be applied, and it should overlap the angles and edges of the wound far enough to have a firm hold on the skin. It will do no harm, and it will not prevent, but will rather help, the union, if a little blood oozes under the dressing. The discoloration is objectionable in appearance only. The following day a fresh coating of cotton and collodion will whiten the dressing so that it will be less noticeable.

After four or five days the entire covering may be removed; better still after eight days. Or the dressing may be left on from ten to fourteen days, when it may be easily removed by peeling it off dry or by moistening it with a little ether.

The cases to which this dressing is applicable are numerous and various. I have used it with entire satisfaction in extensive and angular lacerations of the scalp, the skin of the nose, the face, the lips, the ears, the hand, the thigh, and the calf of the leg. And the use of this dressing has been very successful after the excision of glands and small growths.

The advantages of a dressing without sutures which will secure the union of wounds of the bald scalp, the face, the ear, need hardly be mentioned. The cosmetic effect alone is desirable, but if we can dispense with the dread, the pain, the anæsthetic, incident to stitching, and have fewer and finer linear scars, we shall the more defer to the wishes and the comforts of our patients. This dressing will not fail in suitable cases, and usually one has the pleasure of seeing so fine a linear cicatrix as to suggest a wrinkle in the skin rather than the tracing of a wound.

259 Park Avenue.

Prostatic Obstruction.—My present feeling is, that prostatectomy offers a distinctly better prospect of relief than orchidectomy, and is especially applicable to the cases in which the obstruction is due to the growth into the bladder of prostatic projections which encroach on the urethral orifice.—A. T. Cabot, *Boston Medical and Surgical Journal*, vol. cxl., No. 17.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, April 14, 1900.

HYGIENE AND STATE MEDICINE IN THE UNITED STATES.

No branch of medicine is more neglected in this country than hygiene and State medicine; in fact, its importance is almost completely ignored. The opportunities provided for special instruction on the subject are so small as to be scarcely worthy of mention. This seems to be a strange oversight on the part of State and municipal authorities, who should for the sake of its citizens afford the medical man every means of obtaining practical and scientific training in sanitary work. In Great Britain and on the European continent generally the value of the physician possessing a competent knowledge of hygiene is well recognized, and in the former country a physician is not eligible as a medical officer of health unless he holds a special diploma in public health. It is to be hoped that progressive States in America may soon discern the advantage of following this example. In "Medical Education of the Future," an essay by President Eliot, quoted in the January *Bulletin of the University of the State of New York*, is the following intelligent appreciation of the important part which the State, in connection with the physician, should play in the preservation of the health of the people at large:

"State medicine has many objects in view. It aims not only to protect the public health, but also to increase it. In State medicine individualism is impracticable, for it is impossible for the individual to protect himself. The social co-operation, which in our days the State alone can enforce, is needed to promote security against disease and progress toward better average health and longer life. To take all possible precautions against the spread of infectious diseases is simply an act of good citizenship. Nothing but medical supervision will accomplish the objects of State medicine, and there are no agents so effective as physicians to spread through all classes of the community an educated sense of sanitary decency. Only the State can guard against dirty milk, corrupted water supplies, impure ice, adulterated drugs, spoilt meat and fruit, and filthy and overcrowded tenements. Only the State can enforce the isolation of cases of contagious disease, the suppression of epidemics, and the exclusion of pestilences, like cholera and yellow fever. In exercising such control the State needs every aid which medical experts in chemistry, bacteriology, and comparative pathology can place at its disposal. The medical profession itself hardly recognizes as yet how great promise there is in the further study of the connections between diseases in animals and in man—connections which smallpox, scarlatina in cows, tuberculosis in men and animals, and diphtheria already illustrate. Not even the State—that is, a single state or nation—can deal effectively with such a problem as the suppression of cholera or yellow fever. That is an international problem. The evils which the social and gregarious instincts of men create, by inducing the modern crowding into cities, must be socially remedied; and the most effective force which society can exert to this end is the influence of the highly trained medical officer. Every physician should be a medical philanthropist and missionary, zealous to disseminate knowledge of public hygiene."

BURIAL ALIVE.

FOR all popular fears there is probably some germ of truth—often infinitesimal, and generally magnified and distorted. Among the most dreaded of these, and not improperly so, is the fear of burial alive. It seems not impossible that under rare and exceptional instances such an occurrence could happen, but the authentic cases on record are exceedingly few in number. An accident of this kind is conceivable only if burial is undertaken within a short time of death, as has sometimes been practised during the prevalence of epidemics of virulently contagious disease, and a sufficient interval is not permitted to establish the certainty of death by the beginning of putrefaction.

Several instances that illustrate the possibility of burial alive, though they cannot be said actually to prove its occurrence are related by the Rome correspondent of *The Lancet* (Febrary 24, 1900, p. 582). It is recorded that shortly after the great cholera visitation in Italy in 1866, Pacini, at the time professor of anatomy in Florence, cited cases in which patients certified as dead had returned to life on the way to the cemetery. In the next epidemic of cholera in 1884 a well-known physician of Turin was attacked by the disease, and, worn out by professional duty, failed to rally. Certified as dead, the body was prepared for the undertaker, but after a time consciousness returned. The man failed, however, to rally, and finally died. Recently, in southern Italy, it is reported, a young woman apparently died as the result of an exceedingly difficult laborn ecessitating much unavoidable intervention, the fœtus also being given up as dead and remaining in utero. In accordance with Italian custom the funeral was fixed for the next day and the body was left in a coffin in the mortuary chapel adjoining the cemetery. Early in the morning a photographer, who was commissioned to secure a likeness of the woman, obtained permission to open the coffin, and he found that the body, which had been placed upon its back, was now on its side, and close to it was a "lovely" child without arms, as these had been detached in the obstetric manipulations. The custodian of the chapel now recalled that during the night, while a storm was raging, he had heard feeble cries, as of some one calling for help, from the mortuary chapel. An official inquiry is to be made. This is certainly a remarkable story, and, before accepting it as an instance of burial alive in the form in which we have quoted it, we would prefer more convincing evidence. In commenting upon this report *The Lancet* points out the unlikelihood of the child being born alive, as the mutilation to which it had necessarily been subjected would seem to preclude the possibility of its survival. Post-mortem expulsion of the fœtus is not unknown as a result of the muscular rigidity that occurs after death. In a later letter the correspondent of *The Lancet* at Rome reports another case in which an old countryman fell ill, failed to recover, was certified as dead, and was laid in his coffin with the despatch characteristic of Italian custom on such occasions. As the lid of the coffin was being screwed down the man was felt to move and heard to speak. Medical aid was at once invoked and consciousness restored, but the patient failed to rally, and real death took place in the course of two days.

There was recently reported in the newspapers, from the city of Rochester, the case of a man, thirty-five years old, who became unconscious in the course of an attack of scarlet fever and was pronounced dead, burial taking place two days later. A short while afterward the father of this man died, and to accommodate his remains it became necessary to disinter those of the son. When this was done the glass front of the coffin was found, according to the report, shattered to pieces, the bottom kicked out, and the sides considerably sprung. On removing the lid the body was found resting on its face, the arms bent at the sides, and handfuls of hair tightly clenched in the fingers. Comment upon this account seems scarcely justified further than to say that its correctness does not appear to be probable.

While we have no wish to deny the possibility of burial alive, and while its impossibility is not susceptible of demonstration, we may safely allay any fears that the condition is other than most exceptional.

THE PREVALENCE OF INFLUENZA.

There is reason to believe that influenza has been unusually virulent during the past winter. The records of the Philadelphia bureau of health show that for the week ending March 31st there occurred in that city 679 deaths, being 42 more than during the preceding week, and 175 more than during the corresponding week of the previous year. Of this number 151 were due to pneumonia, 60 to pulmonary tuberculosis, 56 to disease of the heart, 29 to influenza, 26 to old age, 20 to nephritis, 21 to measles, 20 to inflammation of the stomach and bowels, 17 to convulsions, 15 to bronchitis, 15 to apoplexy, 15 to diphtheria, 14 to marasmus, 14 to uræmia, 13 to typhoid fever, 13 to inanition. These figures show the fatal prevalence especially of diseases attributable to cold—the diseases of the lungs and catarrhal conditions, as well as of influenza and its complications.

For the week ending April 7th there were reported 732 deaths—53 more than for the preceding week, 146 more than for the corresponding week of last year, and 313 more than for the corresponding week of 1898. Pneumonia is credited with 144 deaths, congestion of the lungs with 14, bronchitis with 24, pleurisy with 4, pulmonary tuberculosis with 66, diseases of the heart with 52, influenza with 42.

THE STRUCTURE AND FUNCTION OF THE KIDNEY.

In the presence of certain grave conditions of the kidney, as for instance laceration, suppuration, hemorrhage, the surgeon is at times confronted with the question whether it were better to ligate the afferent or the efferent vessel, or to perform nephrectomy.

As the result of experimental observations undertaken with the object of shedding light upon this important subject, Alessandri (*Revue de Chirurgie*, 1899, Nos. 8 and 9) has found that ligation of the renal vein gives rise at first to marked stasis, which interferes greatly with the nutrition and the function of the renal epithelium, almost completely suppressing the secretion of urine. After a time a certain degree of collateral venous circulation is restored, and this may be sufficient to compensate wholly for the obliteration of the renal vein. The volume and the weight of the kidney, which at first are greatly increased, rapidly diminish; and the signs of stasis disappear. While one portion of the organ, in which the circulatory equilibrium becomes re-established, resumes its vitality and its function, other portions of the kidney are destroyed, sometimes by anæmic necrosis, but more often by hemorrhagic infarction, and the newly formed epithelium accumulates in the greatly altered lacunæ of the tubules. In consequence in many instances, after a time, the structure of the kidney is found preserved and its function almost normal. This restitution may permit the kidney to sustain the eliminative functions of the organism if the activity of its fellow should be abruptly suppressed. For this reason the deduction is made that in case of wound or other lesion of the renal vein ligation should be preferred to nephrectomy.

Ligation of the renal artery is followed by deficient *vis a tergo*, with the phenomena of anæmia due to sudden cessation of the nutritive arterial flow. The manifestations of stasis disappear with the establishment of a collateral arterial circulation, particularly in the cortical structure. The phenomena of anæmic necrosis may progress to necrobiotic infarction when the compensatory arterial circulation fails to take place or is inadequate. These zones may be more or less extensive, and they may occupy the entire renal parenchyma, as they do in the cat. In the dog, on the other hand, the collateral circulation may be so fully established that the integrity of the kidney is almost completely restored, and, although this has never been done, it may be possible to remove the other kidney successfully. In the cat, therefore, nephrectomy is to be preferred to ligation of the artery, while in the dog ligation is the preferable practice. In man, the possibility of a collateral circulation through the adrenal, the diaphragmatic, the lumbar, and the ureteral arteries justifies the conclusion that results similar to those in dogs may be looked for.

Simultaneous ligation of both renal artery and vein is incompatible with the continuance of the vitality and the maintenance of the function of the epithelial elements of the kidney. The collateral vascular anastomoses are sometimes sufficient to prevent rapid necrosis of the organ. On the other hand there may be a gradually progressive cirrhosis, which little by little destroys the remaining canaliculi and glomeruli. In consequence, if, after ligation of both the renal artery and vein, the functional portion of the kidney is not preserved, the organism is not exposed to the danger of rapid necrosis of the renal tissue, which still retains a certain vitality and is capable of fibrous transformation through proliferation of the interstitial connective tissue.

THE RESIGNATION OF DR. McBURNEY.

The resignation of Dr. Charles McBurney from the staff of the Roosevelt Hospital deserves more than a passing mention, for it marks the close not only of a personal hospital career of singular value and brilliancy, but also apparently of an important experiment in hospital management.

Some fifteen or eighteen years ago the managers of the Roosevelt Hospital, under the inspiration of the late Dr. Henry B. Sands, established a continuous surgical service under a single head. In 1888 Dr. Sands gave place to a successor of his own choice, Dr. McBurney, under whom the plan has been continued for twelve years, and who has made it for the greater part of that time the most notable surgical service in the country. It is a duty, as well as a pleasure, to testify to the fidelity, the devotion, and the skill he brought to it, and to the brilliant results he has obtained.

But it must also be recognized that the work has been so heavy that without such faithful and skilful service as he has given it could not have been properly done, and it is not surprising that a new generation of managers should feel that they cannot count upon always commanding an equally good supply for the position and should modify their organization accordingly, as it is reported that they have done.

The service has been divided, and Drs. Bull and Weir, whose eminent positions are known to all, have been appointed to the two divisions.

This reduces each service to about forty beds, a smaller number than that found in some other hospitals, and deprives Roosevelt of the unique character heretofore given to it by the size of the service and by the singleness of its control. The change is probably even more marked than these facts indicate, for it must include also a severance of the close relations that have heretofore existed between the hospital proper and its out-patient department, and a loss of the advantages coming from the control and influence of a single chief extending down through all the departments, and the support and enthusiasm of subordinates closely in touch with him.

The hospital, therefore, ceases to have for the profession the peculiar interest which it has heretofore had, and we have only to note the results of the experiment which has been conducted there for the past decade and a half, distinguishing so far as may be between those due to the system and those due to the character and abilities of individuals.

The service has become most notable. No other hospital in the city can show for the same period so important a list of operative cases and successes, and such noteworthy additions to surgical therapeutics and methods. The fame of the hospital has spread, and its reputation has brought patients to it in constantly increasing numbers.

The effects of organization under a single head appear, so far as they can be separated from those of the personal qualities involved, in the exceptionally high standard of methods and results, and in the training of those who at various times have held the subordinate positions. Halsted, Hartley, and Johnson served there for many years. It is enough to mention their names; and they served not only as substitutes in the absence of the attending surgeon, but also as his assistants in important operations and at the clinics, aiding in and profiting by his experience and methods. In this manner experience was widened beyond a single life, and a greater continuity was given to the ideas developed thereby.

Another striking fact, which appears to be an effect of the weight of the service, is the age at which the two surgeons who held the position resigned from it, Sands at fifty-seven, McBurney at fifty-five, while continuing in private practice.

We extend to Dr. McBurney the expression of our warm appreciation of what he has done in the past, and our best wishes for the future, and we congratulate the community and the profession that they are still to have the benefit of his valuable services. To his worthy successors we commend his example, and offer congratulations accordingly.

News of the Week.

Brinton Professorship of American Archæology and Ethnology.—It is proposed to perpetuate the memory of the late Dr. Daniel G. Brinton by endowing in his name a professorship of American archæology and ethnology in the University of Pennsylvania. Dr. Brinton shortly before his death presented his valuable library to the university, in which from 1886 he occupied the chair of American archæology and linguistics.

Treatment of Fractured Patella.—At a meeting of the Orleans Parish (La.) Medical Society, on March 25th, Dr. E. D. Martin demonstrated a new method for the treatment of fractures of the patella. The method proposed is the fixing of the fragments in apposition and securing them with silver staples driven into the anterior surfaces. At least two staples were to be used, placed at different angles to prevent lateral motion. Several specimens of patellæ united with staples were shown to demonstrate the action of the method. Dr. Martin proposed to apply the same method in ununited fractures of the long bones, and especially those of the inferior maxilla.

Jefferson Medical College.—Dr. Francis X. Dercum has been elected professor of neurology and Dr. J. Chalmers Da Costa professor of the practice of surgery and of clinical surgery.

University of Pennsylvania.—At a recent meeting of the board of trustees of the University of Pennsylvania it was decided to reorganize the department of surgery by the election of a professor of surgery and two professors of clinical surgery.

The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons of Columbia University for 1900 will be delivered at the New York Academy of Medicine, No. 17 West Forty-third Street, on the evenings of April 18, 24, and 26, 1900, at 8:30 o'clock, by Prof. John G. Curtis, M.D., of Columbia University. Subject: "The Discovery of the Nerves and of their Function."

Membranous Croup a Notifiable Disease.—At a recent meeting of the Philadelphia bureau of health the following preamble and resolution were adopted:

"*Whereas*, Diphtheria and membranous croup are considered by the medical profession as identical diseases; therefore be it

"*Resolved*, That hereafter all cases of membranous croup reported to this office be considered and recorded as diphtheria."

St. Joseph's Hospital Training-School for Nurses, Yonkers, N. Y.—At the commencement exercises for trained nurses, held March 29th, the following young ladies received the highest honors of the training-school: Anna J. Collins, Newport, R. I.; Anna St. George, Wappingers Falls, N. Y.; Anna M. Bissett, Nova Scotia; and Mary E. Duffin, Lockburn Province, Quebec. A history of the training-school was read by Dr. A. C. Benedict, and the address to the graduates was delivered by Dr. Valentine Browne, after which Dr. P. A. Callan presented the diplomas to the graduates.

College of Physicians of Philadelphia.—At a stated meeting held April 4th Drs. W. H. Keen and W. G. Spiller presented a communication entitled "Multiple Neurofibromata of the Ulnar Nerve." Dr. S. Weir Mitchell read a paper on "The Manuscript Letters of Jenner in Possession of the College," which are not known to have been published hitherto. Dr. Laurence F. Flick read a paper entitled "The Registration of Tuberculosis." Dr. John Chalmers Da Costa read a "Report of a Case of Hip-joint Amputation." The patient was a girl, fifteen years old, in whom a new growth rapidly appeared in the upper part of the thigh, and so involved the vessels as to preclude the application of the ordinary methods of hæmostasis. Accordingly, digital compression of the external iliac artery against the psoas muscle was made in accordance with the suggestion of McBurney, and the femur was disarticulated Recurrence, however, took place in the stump. On histological examination the growth was found to be a small spindle-cell sarcoma. Dr. Robert G. Leconte reported the case of a young man, eighteen years old, in which amputation through the acetabulum was performed for a large spindle-cell osteo-sarcoma of the thigh. Dr. Richard H. Harte presented for himself and others a large portrait in oil of Dr. John Ashhurst, Jr.

The American Gastro-Enterological Association.—The third annual meeting of this association will be held in Washington on May 1st, under the presidency of Dr. Max Einhorn, of this city. The sessions, at 10 A.M. and 2:30 P.M., will be held at the Shoreham.

A German Report on the British Sanitary Service in South Africa.—Drs. Krummacher and Schmidt, German army surgeons, who returned recently to Berlin from the British camps in South Africa, are reported to have spoken in commendation of the sanitary arrangements there. They deny that Dum-dum or other expanding bullets are used by the British, and assert that they did not witness a single instance of actual breach of the rules of the Red Cross Society.

The Adirondacks Hospital.—Acting under an emergency message from Governor Roosevelt, both houses of the legislature passed on April 5th the Davis-Hill bill for a State sanatorium in the Adirondacks for the care of persons suffering from incipient pulmonary tuberculosis. The bill was amended to reduce the appropriation from $150,000 to $50,000. In the Assembly a motion to reconsider the bill was lost by a vote of 91 to 14.

Mountain Toothache.—An observation of Mr. Hafner, of Zurich, published in *Die Natur*, forms a curious contribution to medical geography. He finds that all the engineers and workmen on the Jungfrau railway who are obliged to remain a considerable time at altitudes of about 2,600 metres above the sea level are liable to a disagreeable complaint. After eight or ten days they are seized with violent pains in several teeth on one side of the jaw, the gums and cheek on the same side becoming swollen. The teeth are very sensitive to pressure, so that mastication is extremely painful. These symptoms increase in severity for three days, and then gradually and entirely disappear. It seems to be purely a phenomenon of acclimatization, for all new-comers go through the complaint, and it appears never to recur.—*Janus.*

Insanity in the Army.—In reply to a Senate resolution, the secretary of war has prepared a statement in regard to insanity and suicide among the troops in the Philippines. The statement shows a smaller rate of insanity among the troops in the Philippines than in the regular army for ten years. It says that from late in July, 1898, to March 20, 1900, 35 cases of insanity have been reported from the Philippine Islands. During this period the mean strength of the force under General Otis was 32,000 men. Based on this strength the rate of insanity for twelve months was 31.3 cases. The mean strength of the regular army for the ten years ending July, 1898, was 29,000 men with a rate of insanity of 33.1, 7 officers and 22 enlisted men committing suicide in the Philippines between April 11, 1899, and March 27, 1900. The statistics on this subject embrace the period from the ending of the war with Spain, and the mean strength of the Philippine army from that time to March 27, 1900, is given as 47,800. Based on these figures the rate of suicide is reported as 30.7 for the year, or about .64 per thousand. In the regular army for ten years, with a mean strength of 29,000 men, the rate of suicide was 18.4, or about .63 per thousand. Another comparison is shown by the table giving the number of casualties each year in the regular army. In 1891, with 26,000 men, there were 22 suicides; 1892, with 26,000 men, 22 suicides, and in 1893, 22 suicides among 27,000 men. The conclusion drawn from these figures is that the statements regarding the increase of suicide and insanity in the army are entirely unsupported by the facts.

The American Climatological Association will meet in seventeenth annual session at the Arlington, Washington, on May 1st–3d, under the presidency of Dr. A. Jacobi, of this city. The sessions will be from 10 A.M. to 1 P.M. each day. The annual dinner will take place on the evening of May 1st.

The Indian Famine.—Nature holds out no prospect of relief to the famine which has prevailed so long in India, but on the contrary there is every prospect that the conditions will be worse this year than last. In the course of a recent speech on the budget, the viceroy, Lord Curzon, said the loss to the wheat crop, caused by the drought during the present year, was from £8,000,000 to £10,000,000. He added that the loss to the cotton crop was £7,000,000, while the oilseed crop, usually covering eighteen million acres, was non-existent outside of Bengal and the northwest provinces. The loss to cultivators in Bombay alone, in food crops, was £15,000,000 and in cotton £4,000,000. It was impossible, he said, for any government to anticipate the consequences of a visitation of nature on so gigantic and ruinous a scale.

Professor Neisser, of Breslau, has been made the subject of a sharp debate in the Prussian Diet for having performed some unwarranted inoculation experiments. The facts of the case, as stated by the Berlin correspondent of *The Lancet*, are briefly as follows: Professor Neisser injected sterilized blood serum of syphilitic persons into prostitutes and into two children in order to immunize them against the disease. The experiment had no bad sequelæ whatever. Several years afterward some of the prostitutes suffered from syphilis, which first manifested itself on the genitals, so that the attempted immunization had proved a failure. That they had been infected by the injection, as was alleged by Professor Neisser's adversaries, was quite impossible owing to the length of time between the giving of the injections and the appearance of the syphilis, together with the fact that none of the patients other than the prostitutes contracted the disease. These facts were gravely misrepresented by different speakers, Professor Neisser being said to have injected syphilitic virus in order to see whether it was contagious or not. Several members of the Diet asked the minister of public instruction if Professor Neisser had been or would be prosecuted for what he had done. The minister, Dr. Studt, and the chief of the university department, Herr Althoff, stated that Professor Neisser had not performed his experiments for frivolous reasons, but for the eminently humane purpose of combating syphilis. They said that he no doubt erred in making experiments on patients without previously asking them whether they consented to the injections or not. The minister admitted that he might have been prosecuted under the criminal law, but as the acts complained of were committed six years ago there was, under the circumstances, no likelihood of a prosecution. The government had not yet considered whether it would be advisable to make use of its disciplinary power over him as a professor of a State university.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 7, 1900. March 31st.—Passed Assistant Surgeon J. C. Rosenbleuth ordered to the *Wilmington* sailing from New York City, April 5th, to join ship at Rio de Janeiro, Brazil. Passed Assistant Surgeon F. C. Cook detached from the *Wilmington* and ordered to proceed home by mail steamer. April 2d.—Surgeon F. Urie commissioned surgeon from October 25, 1899. Passed Assistant Surgeon W. M. Wheeler commissioned passed assistant surgeon from May 27, 1899. Passed Assistant Surgeon D. N. Carpenter commissioned passed assistant surgeon from October 24, 1899. Passed Assistant Surgeon F. L. Pleadwell commissioned passed assistant surgeon from October 25, 1899. April 3d.—Passed Assistant Surgeon W. F. Arnold detached from the naval hospital, Norfolk, Va., and granted leave for three months. Passed Assistant Surgeon G. D. Costigan detached from the naval hospital, Chelsea, Mass., and ordered to the Boston navy yard immediately. Assistant Surgeon D. N. Carpenter detached from the Boston navy yard and ordered to the naval hospital, Chelsea, Mass., immediately.

The Plague.—The epidemic at Honolulu being now at an end, no case having been reported since March 25th, the public is beginning to count the cost. It is estimated that the bill for fighting the disease there will come to at least $2,000,000. A large part of the expense was incurred in finding homes for the persons who were burned out by the fires, particularly the conflagration of January 20th. The building and provisioning of the detention camps have been costly, and the salaries of physicians, at $250 per month, have amounted to a large sum, to say nothing of paid inspectors, fumigators, heads of departments, etc. From December 12th to March 31st there had been seventy cases of plague in Honolulu, of which sixty resulted fatally. Nine patients were cured, and one was still in the hospital at the end of March, but was in a fair way to recovery.—In Manila, we learn from a correspondent of the Associated Press, the disease has prevailed for about three months, but little anxiety is felt by the foreigners. During the first two months of its prevalence there had been over two hundred cases, according to the estimate of the health officials, and about eighty per cent. of these had resulted fatally. The sanitary measures have been simple but effective, consisting in the enforcement of cleanliness, as far as possible, and in a system of inspection by Filipino and Chinese employees. There are now one hundred inspectors at work in Manila, thirty of them Chinamen and the others Filipinos. They are sent out in squads, usually two Filipinos and a Chinaman with a soldier to boss them and see that they do their work and abstain from blackmailing. Whenever a plague victim is discovered he is sent to the Chinese or Filipino hospital if it is possible to move him. The house is thoroughly disinfected, a bonfire is made of everything movable, a yellow placard announcing "bubonic pest" appears on the door, and a sentry stands guard to keep persons away. For four days the house is kept closed and the inmates are isolated. When two or three cases develop in one street, the street is barred against business. Two-thirds of the cases have been among the Chinese coolies, and the rest among the Filipinos, the whites having thus far escaped.

Dr. William Camac died at Philadelphia on April 3d, at the age of seventy-one years. He was graduated from Jefferson Medical College in 1852.

Clinical Department.

A CASE OF IODOFORM POISONING IN AN INFANT TWO WEEKS OLD.

By J. C. JOSEPHSON, M.D.,

BALTIMORE, MD.

Recently I was called to see Hillel B——, two weeks old, with the following history: The child had been circumcised six days previously, and as the wound would not heal well the mohel (circumciser) gave the mother a salve to apply. This again proving unsatisfactory he changed it on the day previous to my visit for a yellow salve. The following day the child was very somnolent, had stridulous breathing, and refused the breast. I found the child comatose, cyanosed, with feeble but stridulous breathing, and retraction of the epigastrium, evidently from laryngeal spasm. The pupils were contracted to the size of a pin point. No paregoric had been used, nor any of the patent nostrums for which the baby cries. There was a strong odor of iodoform about the child. On removing the diaper I found the following condition: The circumcision wound had not yet healed; the whole under surface of the penis, the scrotum, and the inner surface of both thighs were the seat of an eczema, so severe as to bleed on contact. The temperature was 100° F., the heart action feeble. I will not detail the measures adopted—as the hot mustard bath, friction with alcohol and with mustard, a hot enema and stimulation with a few drops of brandy now and then. As I considered the child moribund, I declined to prescribe any internal remedies. An hour later, however, I was called again. The child had regained its color after the bath, but had just had another attack of apnœa with cyanosis. The parents importuned me to "do something for the child." As some of the symptoms resembled opium poisoning, belladonna suggested itself to me, which I prescribed in ♏ i. doses of the tincture to be given every hour till seen again. The following morning, to my great surprise, I found the child in an almost normal condition—with healthy color and breathing, good pulse and normal temperature—except that it was still somewhat somnolent and that the pupils were dilated from the belladonna. The parents told me that it had had another attack of apnœa with cyanosis in the middle of the night, when the mustard bath was repeated. The eczema had wonderfully improved over night. The child has been well since then.

Wood describes a form of iodoform poisoning with contracted pupils and coma, and I am convinced that this was such a case, for the following reasons: No opiate in any form had been used to account for the extremely contracted pupils; there was a strong odor of iodoform about the child when I first saw it; the symptoms set in soon after applying the "yellow salve"; the violent eczema improved so rapidly after washing off the salve in the bath that on the following morning the affected skin was perfectly dry and only of a delicate pink in place of the angry red of the night before.

I am inclined to ascribe here some antidotal or rather antagonistic virtue to the belladonna. The laryngeal spasm is worth noticing as a symptom.

A COMPLICATION OF MISCARRIAGE WITH APPENDICITIS, DUE TO TRAUMATISM.

By CARL D. S. FRÜH, M.D.,

PHILADELPHIA, PA.,

ASSISTANT DEMONSTRATOR OF ANATOMY, JEFFERSON MEDICAL COLLEGE.

Mrs. A——, aged twenty years, pregnant seven months, primipara, was passing from the kitchen of her house to the ground, when she suddenly slipped, and being in danger of falling she grasped a support, severely twisting her body, as she herself describes it. From this moment for eleven days she was in constant pain and discomfort, matters finally getting so bad that the writer was sent for. The patient was in dire distress (temperature, 104.5° F.); she was constantly vomiting matter admixed with bile, suffering intensely with every such attack; there were hiccough, tympanites, tenderness of the entire abdominal region, intense agony when she passed water, the simple action of the muscles involved in this act causing the greatest suffering; movement was almost impossible on account of the pain. Constipation was present for some five days. A slight show was in evidence; after four days the fœtus and placenta were delivered, with relief from the intensity of pain for some twelve hours, when there was a repetition of the above symptoms, with pains passing from the epigastrium to the left inguinal region, then to the right side. There being no flow whatever after the delivery of the fœtus and placenta, one would naturally have supposed that all this severe state of the patient was one due to sepsis, and that the womb must be curetted to remove the offending cause. The symptoms here, however, led the writer to appreciate the condition of a typical traumatic appendicitis, and the final recovery of the patient would seem to prove the diagnosis correct. There was no return of the flow.

The writer has omitted all detail of the medical treatment, wishing merely to call attention to the possible error of judgment which might have tempted one to locate the material fault in the uterus. Every diagnostic point of appendicitis was borne out in this case.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 5, 1900.

Conservative Operation for Uterine Fibroids.— R. A. Kingman reports two illustrative cases, and urges conservatism, especially in young women. Certain cases undoubtedly demand hysterectomy, but whenever possible the endeavor should be toward the preservation of functional integrity of the pelvic organs. Neither size nor number of tumors should be necessarily a bar to this attainment, nor should the fact that at a single sitting we cannot entirely clear the uterus of nodules compel the sacrifice of that organ. The author praises Dr. Burrage's morcellation forceps, which do not wound a flat or concave surface but will cut or strongly seize any projecting mass. The frequent association of ovarian disease with fibroid tumors will make it necessary at times to resect or do other conservative operation upon one or both ovaries, for it must not be forgotten that removals of the new growths will be followed by uterine involution and by greatly improved conditions in the appendages as well.

A Peculiar Case of Adeno-Carcinoma of the Body of the Uterus.—Agnes C. Victor reports the case of a woman, aged sixty-seven years, in whom apparent temporary improvement of an adeno-carcinoma followed the administration of tablets of mammary substance. By abdomino-vagino-rectal examination a hard nodular tumor was found apparently springing from the posterior wall of the body of the uterus, extending up into the fundus and projecting backward into the cul-de-sac. A vaginal hysterectomy was performed, and on attempting to deliver the fundus it suddenly fell to pieces in the operator's hand, and she had only a handful of pieces of soft tissue. The posterior wall of the uterus was found to be perfectly smooth and regular, with no sign of a tumor, this being on the anterior wall and projecting into the uterine cavity. The posterior wall was a mass of soft tissue retained only by a paper-like layer of peritoneum.

A Case of Extra-Uterine Pregnancy.—Frederick W. Johnson describes a case of ruptured extra-uterine pregnancy. Laparotomy was performed, and a greenish-yellow tumor, the size of an orange, found adherent in the pelvis and connected with the left Fallopian tube, while the thickened right tube was adherent to it. This mass was removed, and the sac-like dilatation was found to be filled with clotted blood, which was in layers and considerably decolorized. At one end of the mass was a little thready tissue. On microscopical examination there were found fine branching filaments of a fibrous character terminating in round, enlarged ends, similar to the chorionic villi in the first half of pregnancy. In the ovary was a large cystic cavity filled with blood (corpus hæmorrhagicum). No true corpus luteum was found.

Empyema of the Frontal Sinus.—John D. Paige reports a case of empyema of the antrum of Highmore, bilateral empyema of the ethmoid cells, and empyema of the frontal sinus on the left. The antrums were opened and drained through the alveoli, and the ethmoid cells opened and curetted; the frontal sinus was irrigated through the enlarged natural opening, with great relief to the symptoms and discharge. An *x*-ray picture shows the existing conditions.

On Distortion of the Spine.—J. W. Courtney reports two cases of diplegia brachialis due to distortion of the spine, which he defines as a pause in the act of luxation. The author gives the symptomatology of the affection, and says that the determinate factor in its diagnosis as against fracture or luxation is the absolute failure to discover any change in contour or abnormal mobility of the spine. If the patient has a tuberculous taint, the process may become chronic, otherwise the prognosis is good. Treatment consists of rest in bed with support and immobilization of the neck, with very slight extension of the spine.

The Conservative Operative Treatment of Fibroids.—N. L. Burrage reports three cases. The first consisted of abdominal myomectomy, removal of eleven subperitoneal nodules and the right ovary. The second was a vaginal myomectomy, removal of fibroid nodule of subperitoneal evolution from the front wall of the uterus by anterior colpotomy. The third was morcellation of submucous nodule at fundus, and polyp with pedicle springing from fundus. The author considers it a greater glory to patch up a diseased organ and put it in fair working condition than to remove it because it may cause trouble in the future.

Journal of the Amer. Med. Association, April 7, 1900.

Curious Facts You Find in General Surgery.— The first case reported by Lucien Lofton is that of a negro who had been struck on the head with an axe, with the result that the external temporal and the transverse facial arteries had been entirely severed, besides a number of peripheral arterial twigs; the outer and inner tables of the skull were crushed, while internally the middle meningeal artery was severed, and the meninges suffered greatly. This man was on his feet in forty-eight hours, and in twelve days he had resumed his position as a sawmill hand. The writer dismissed him after the third dressing, and his recovery was uninterrupted. The second case was that of a negro who, in spite of a broken radius, held his position as a sawyer for ten days, working steadily twelve hours a day with little or no inconvenience. The third case was one of cornu cutaneum in a man aged seventy years. It was removed under cocaine anæsthesia and healed by first intention. Three months after the patient returned with another horn springing from the original core. This was removed together with all horny cells, resulting in complete enucleation. The fourth case was a shattered humerus in a boy ten years old, which had been neglected by his family for three weeks. Operation resulted in a perfectly sound arm.

Diagnostic Value of the Deep Reflexes of the Lower Extremities.—D. S. Fairchild says that in a case of motor or sensory paralysis, or both combined, the questions which will occur to the examiner are three in number: (1) Is the paralysis due to an organic change in the anterior or motor side of the spinal cord, or in both anterior and posterior sides, or are the lines of communication impaired or destroyed by injury to, or disease of, the afferent or efferent nerve-fibres, or both? (2) Is the paralysis hysterical in character? (3) Is the paralysis feigned? The author then considers the differential diagnosis of various forms of paralysis and says the real diagnostic value of the deep reflexes can be determined only by a very careful consideration of the facts in the case, and by a careful study of the reflex itself. There is no certain and absolute guide to the intensity of a normal reflex.

Differentiation between the Bullous, Vesicular, and Pustular Eruptions of Early Life. — Charles Warrenne Allen says that although dermatologists cannot invariably distinguish betwen rare forms of bullous affection, or classify them in an acceptable manner, it is usually no hard matter to distinguish the non-specific from the specific. This is a general rule to which there are few exceptions. But the subject, even when thus restricted, remains a very broad one, and in order to cover the ground the writer takes up the various bullous, vesicular, and pustular affections of the skin, showing some of the points of differentiation between them and syphilis. He thus considers pemphigus, pemphigus acutus, pemphigus neonatorum, pemphigus chronicus, pemphigus epidemicus, pemphigus foliaceus, epidermolysis hereditaria bullosa, dermatitis herpetiformis, impetigo, ecthyma, hydroa, and generalized vaccinia.

Uniformity in Definition and Application of the Terms Position and Presentation.—Frank A. Stahl deplores the unfortunate ambiguity of definition and application of terms in descriptive obstetrics. The writer says that although at the meeting of the Ninth International Medical Congress held in Washington, D. C., in 1887, the committee cleared up much that needed simplifying, still many inequalities remain. So far as pertains to uniformity in definition and application of the two terms "position" and "presentation," they are not synonyms and should not be used synonymously. Etymologically considered, position refers to "aggregate of spatial relation of a body or figure to other bodies or figures; the situation; the place of a thing." Presentation refers "to that which is before; in view; appearance."

Uric Acid and the Serious Results when Not Eliminated.—M. S. Marcy speaks of the serious results that follow the taking into the system and retaining an excess of urates. He protests against introducing urates into the system in large quantities by taking into the stomach meat, especially extracts, containing 63 grains of urates to the pound; tea, 174; coffee 70, and cocoa 59 grains to the pound, as well as many other foods and drinks containing a less amount. The author concludes that if we would enjoy the best of health we should leave out of our diet all foods and drinks containing a large amount of urates, and live on a vegetable, cereal, fruit, and milk diet.

Pathological Changes Occurring in the Unobstructed Nostril in Cases of Deviated Septum.—E. Larue Vansant says that these changes in a case of marked deviation of the septum may be divided into three stages: The first stage, that of hyperplasia of the tissues from over-function, is a compensatory hypertrophy; the second is that of atrophy from inflammatory changes; and the third that of atrophy associated with sepsis of the nasal chamber and accessory sinuses. When the deflection is very moderate a slight compensatory hypertrophy of the turbinals of the more open nostril may be the only pathological change noticeable.

A Case of Rhizomelic Spondylosis.—Augustus A. Eshner reports this case. He says that though the disease has been known for a long time, particularly to surgeons, unusual attention has been directed to it of late, and reports of cases have been made from all parts of the world. The writer says of this case that it would appear from the symptoms and physical signs that the disease is one not only of the vertebra and its appendages, but also of the spinal cord. Also the history of rheumatism obtained may be significant from an etiological point of view, as it has been thought to play such a rôle in other cases of the kind.

Dilatation of the Ophthalmic Veins; Cure.—R. Ortega reports the case of a woman, thirty-two years of age, who had exophthalmos and complained of intense pain on one side of the head. An orbital tumor was diagnosed, and operation revealed a dilatation of the ophthalmic veins. The eye was enucleated with relief to the symptoms.

Medical News, April 7, 1900.

Malignancy.—Arthur L. Fuller sums up his remarks on this subject by saying that malignancy is a term which implies some special form of pathological activity, not present in other conditions. Since the cachexia alone seems to depend on forms of cell energy which are absent in other conditions, it alone must be considered the essential feature of malignancy. The relation of cachexia to the embryonic character of the tumor cells is such as to suggest that it is due to the retention of products of embryonic cell metabolism in the system, constituting a form of toxæmia. This suggestion is borne out by the fact that the presence of embryonic cells pouring their metabolic products into the system in the absence of the thymus gland, constitutes a pathological condition similar to those present in myxœdema and Addison's disease. Therefore the administration of thymus in malignant disease might prove useful to sustain the strength, as the administration of thyroid has done in myxœdema, and of suprarenals in some cases of Addison's disease.

Cancer of the Breast.—Robert Abbe says that progress toward the cure of mammary cancer has come from the recognition of the anatomical distribution of the lymphatics; that too much emphasis cannot be laid upon the danger of the operative infection of the wound by cutting infected glands and lymphatic channels, or discharging into the healthy wound infected cells squeezed from the parts being removed. Dr. Abbe remarks the improvements in the statistics that immediately followed the adoption of radical surgical methods, and says that such results as three years' immunity are now within the easy reach of all good operators. He finally concludes that a recurrence after operation need not discourage patient or surgeon. If the recurrent growth be speedily and thoroughly attended to there is a strong probability of its eradication, as the recurrence is not a return of the disease, but a continued growth of invisible metastatic foci left at the time of operation.

Hypnotism.—F. X. Dercum says that hypnotism is interesting to physicians from two points of view: First, the explanation of its principles; and, second, the extent of its practical application. The writer then discusses the theory of hypnotism, and the methods and precautions to be observed in its employment. Coming to the question of its practical value to physicians he thinks it of slight value, having a very subordinate place in therapeutics. It can have no pathological effect, and is practically limited in its scope to hysterical and neurasthenic patients.

A Case of Spontaneous Rupture of the Uterus.—Bradford Woodbridge reports a case of this accident in an apparently healthy young woman, before the advent of labor and without history of trauma or premonitory symptoms. The patient had received two years before a blow in the pregnant uterus severe enough, as she believed, to hasten labor, and the writer suggests that as a result there may have been a weakening of the uterine muscle at the point of injury.

Causes, Diagnosis, and Treatment of Cystitis.—Ramon Guitéras discusses cystitis separately in the acute and chronic forms, touching upon the many subvarieties of each during his consideration of causation and treatment.

New York Medical Journal, April 7, 1900.

Puerperal Septicæmia; Especially its Bacteriology and Treatment by Serum.—L. A. Hering regards the streptococcus as the chief source of mischief, but does not believe that the infection is ever purely streptococcic. The staphylococcus and bacillus coli communis are also at work in many cases. The latter germ probably gains access to the parturient tract by the lymph route. Serum treatment often fails because either the serum is old, or there is a mixed infection to deal with, or treatment may be delayed and too little serum given, or the patient may be over-stimulated. Hering does not hesitate to curette, flush out with warm, weak bichloride, and introduce a drain of iodoform gauze. Pus must be removed whenever present; the bowels kept open at all costs; serum injections should be begun early, and be made into sterile tissue under most rigid antisepsis. Large doses of strychnine, gradually tapering off in conjunction with three-grain doses of caffeine sodio-salicylate, can be administered with profit.

A Critical Test of the Justus Blood Test for Syphilis.—D. H. Jones experimented with thirty-five syphilitics and eighteen control patients. He believes that the test has a value in the recognition of doubtful cases of syphilis, but that it often fails in two classes of cases in which early diagnosis is especially desired, viz., in latent cases and in early chancre, and sometimes at the beginning of the secondary stage. He believes, however, that the limitations of the test have not as yet been fully determined. The test is based on the asserted fact that a single inunction of mercury in all cases of untreated cases of secondary, tertiary, and congenital forms of syphilis causes a reduction in the hæmoglobin due to the sensitiveness of the red blood cells to the action of the drug, while in non-syphilitics no reaction follows.

The Treatment of Gouty Deposits.—E. L. H. McGinnis narrates his experience with the use of the lithia salts administered by cataphoresis. The method is described as follows: The fingers are washed off with chloroform; thin sheets of borated absorbent cotton are wrapped around the affected joints and thoroughly wetted with a solution of iodide of lithium. The fingers are then covered with the metal handles of the ordinary galvanic battery, each being connected with a terminal from a cord leading to the positive pole, the negative being a flat metallic plate upon which the other hand is laid. The current is allowed to flow for ten minutes (15 to 25 milliamperes in the case described). Following this the joints are vigorously massaged for several minutes.

Some Critical and Desultory Remarks on Recent Laryngological and Rhinological Literature (Tenth Paper).—J. Wright discusses some of the more recent contributions to the literature of tuberculosis, having to deal especially with modes of infection. He takes up particularly the statements of Lewin, who claims that five per cent. of all adenoids in the naso-pharynx contain foci of latent tuberculosis. This proportion Wright believes to be overestimated by Lewin, though he admits that the difference in the frequency of tuberculosis in European and American cities may easily explain the discrepancy between the figures of different observers.

Chronic Carbon-Monoxide Poisoning.—T. J. Yarrow gives an outline of the chemistry of this compound and enumerates the tests used for its detection. In one case, that of a man aged fifty-two years, who lived in a house in which there was a leakage of gas, and who suffered from the evidences of constantly inhaling it, Yarrow employed bone marrow and tonics with good effect. He believes that this gas leakage in modern houses is a far more common source of bodily ills than is usually imagined.

Creosote: Some Clinical Observations of its Use in Various Conditions.—F. C. Test gives clinical histories of ten cases in which the use of the remedy was followed by good results. The list includes cases of gastro-enteric auto-intoxication as shown in various nervous symptoms, whooping-cough, bronchitis, and tuberculosis.

Philadelphia Medical Journal, April 7, 1900.

The Soldier in the Tropics. — Charles E. Woodruff discusses the question of the soldier's food, the effect upon him of alcohol, and his acclimatization in the tropics. The American ration, he says, is, contrary to the general opinion, one of the least liberal rations among civilized nations. He thinks, however, that the refusal of Congress to change the ration was the point of wisdom. He declaims against the advice not to eat heartily in the tropics. The writer favors the use of alcohol, saying that "experience has demonstrated that in a hot climate the moderate use of intoxicating drink is essential to continued health and efficiency." He does not believe that the white man can become acclimated, and characterizes such an assertion as nonsense.

Intestinal Fever.—G. W. Richardson describes a fever which prevailed largely among the members of the eighth army corps in the Philippines. It was characterized by anorexia, weakness of the limbs, headache, backache, cramps in the stomach, diarrhœa, and fever. The digestive symptoms were the most prominent, the fever seldom being as high as 102° F. The exciting causes of the condition he classifies as: (1) Excessive heat of the sun with insufficient head protection; (2) indigestible and improperly cooked food; (3) unsuitable clothing; (4) drinking of native liquors. The writer speaks far from favorably of the food supplied to the army in the Philippines. As a preventive of diarrhœal troubles he thinks the abdominal bandage is very valuable.

Notes on the Philippines.—Samuel O. L. Potter describes the people, the water-supply, the sanitary condition, and the health of Manila. The city, he says, is a very healthy one, and with moderation in eating, drinking, and working, one need no more be ill in Manila than in New Orleans, St. Louis, or New York. As to heat, "Washington in summer is an inferno compared with Manila," American women and children do very well so long as they remain well, but recovery in case of illness is difficult.

The Share of the White Man's Burden that Has Fallen to the Medical Departments of the Public Services in Puerto Rico.—John Van Rensselaer Hoff gives an account of the establishment of the superior board of health in Puerto Rico, and of the work it has done. He gives the statistics of the work of vaccinating the entire population of the island, which was inaugurated by him, and which resulted in the stamping out of what threatened to be a serious epidemic of smallpox.

The Sanitary Condition of the Far East as it Affects the United States.—Stuart Eldridge speaks of the danger of the spread of infection across the sea which has resulted from the increased speed of ships, and describes the measures which have been taken by the Marine-Hospital service to prevent, by means of systematic inspection of ships at the port of departure, the introduction of any of the epidemic or endemic diseases of the East into this country.

Amœbic Dysentery.—I. B. Diamond reports four cases of this affection contracted in Texas and in Georgia. The treatment which he recommends consists in rectal injections of solutions of hydrogen dioxide or of potassium permanganate. Relapses are frequent, and the writer says that a patient should not be considered out of danger for at least two months after apparent recovery. During that period the patient should remain on a liquid diet.

Cuban Malaria in the North Atlantic Squadron of the United States Navy in 1898.—W. F. Arnold concludes from a study of the statistics of malaria in the navy off the southern coast of Cuba in the summer of 1898, that the disease is water-borne in some cases, while in others the infection would seem to have been spread by mosquitos.

Histology and Microchemical Reactions of Some Cells to Aniline Dyes; Identity of the Plasma Cell and Osteoblast; Fibrous Tissue a Secretion of the Plasma Cells; Mast Cell Elaborates Mucin of Connective Tissues.—H. F. Harris contributes a paper with this comprehensive title.

Bubonic Plague.—H. F. Harris and W. F. Arnold describe the clinical symptoms, pathology, and bacteriology of the plague. They speak highly of Yersin's antitoxic serum and Haffkine's prophylactic serum, though they have had no personal experience with either.

The Methods of Control of Leprosy in the Hawaiian Islands, with a Description of the Leper Settlement in Molokai.—R. S. Woodson recounts the familiar history of the leper colony at Molokai, and gives pictures of three cases of leprosy.

The History and Etiology of Bubonic Plague.—George M. Sternberg gives in the Tower lectures, delivered at Georgetown University, a brief *résumé* of the history of the plague in the middle ages and modern times.

The Parasites of Æstivo-Autumnal (Remittent) Fever.—Charles F. Craig describes the various stages of the cycle of development of the æstivo-autumnal plasmodium in man.

The Hospitals of Puerto Principe, Cuba.—S. T. Armstrong presents an interesting article, with illustrations, of the three hospitals in this city, which he believes to be typical of those of other Cuban cities.

The Lancet, March 31, 1900.

Note on the Superficial and Deep Reflexes.—J. M. MacCormack finds that in the initial stage of general paralysis of the insane there is generally a weakening of painful sensibility and of the cutaneous reflexes with the exception of the plantar reflex. On the other hand, the deep reflexes are exaggerated. In the second stage the plantar reflex is markedly exaggerated and the other reflexes both deep and superficial are increased. In the third stage all the reflexes become weaker and finally disappear. During an epileptiform attack the superficial reflexes are decreased or abolished, but the tendon reflex is exaggerated, and is often accompanied by fibrillary contractions which may be transmitted from a limb to the trunk and then may pass to the limbs of the opposite side. In epileptic insanity sensibility to pain and the skin reflexes are generally lessened, but the tendon reflexes are normal. After some convulsive attacks the tendon reflexes are increased, while the cutaneous reflexes are considerably weakened, with the exception of the plantar reflex, which is augmented and may be associated with trembling or even with epileptoid movements of the foot. Hypochondriacs and neurasthenics generally present an increase of all reflexes both superficial and deep. In hysteria there is a decrease of painful sensibility and of the cutaneous reflexes. In alcoholic paralysis painful sensibility and tendon reflexes are exaggerated, while the cutaneous reflexes (except the plantar reflex) are weakened. In acute mania the reflexes are normal. In secondary dementia all reflexes are exaggerated. In melancholia painful sensibility and cutaneous reflexes are normal, while the tendon reflexes are exaggerated. In the stage of melancholic stupor painful sensations, which on superficial examination may appear feeble, are in reality normal, the cutaneous reflexes are feeble, and the tendon reflexes are exaggerated.

The Typhoid Bacillus and Typhoid Fever: Second Goulstonian Lecture.—P. Horton Smith considers the abnormal varieties of infection and the relation which the bacillus bears to the chief complications and sequelæ of the disease. He believes that we may have the fever without the intestinal lesions. In these cases the bacillus passes into the blood and becomes generalized in the organs without causing lesions in the bowel even though the latter may be the channel of entrance. He then discusses the various complications, paying special attention to bacteruria. Concerning suppurative conditions, he states that it is very common to find the bacillus in pure culture in the abscesses connected with bone, but in suppurations occurring elsewhere its presence is undoubtedly rare. Attention, too, is called to the persistence of the bacilli in the body after recovery. The patient may be in the mean time in perfect health, but under the influence of some passing stimulus the bacilli may resume their activity and give rise now to periostitis, now to osteomyelitis, or it may be to cholecystitis.

On the Abortive Treatment of Suppuration of the Eyeball.—S. Snell counsels the following procedure: Ether having been administered, the cornea, unless it is already destroyed, is divided across by a cataract or Beer's knife. The next step is to remove the remains of the cornea up to the sclerotic, and this can be well done with scissors. After removal, Mules' scoop may be used to aid further in the cleaning of the interior of the globe, or cotton-wool and forceps can be employed to wipe out the contents. Lastly, sublimate solution is freely syringed into the eye cavity until all the contents have been removed or washed away and only the bared sclerotic remains. Gauze is lightly packed into the eyeball and a bandage is applied. Almost immediate relief from pain follows the operation, with no return, and the swelling of the orbital tissues gradually subsides. The dressings are changed on the night of the operation, and during the next few days the eye is syringed twice a day and the gauze is re-applied. For about the first three days there is some discharge; after that practically none.

On the Treatment of the Rheumatic Diseases of the Heart in the Early Periods of their Manifestation.—A. E. Sansom considers that the distinct advances of recent therapeutics which are established by satisfactory evidence are: (1) the employment of salicin and the salicin compounds; (2) the use of the icebag and cold applications; (3) the employment of physical means for directly influencing the nerve mechanism; and (4) the judicious employment of bathing, hygienic methods, massage, and mechanical exercises. In the swollen and dilated heart of rheumatism failing cardiac power is best combated by ammonia and kindred diffusible stimulants in small doses of camphor water or with musk in doses of gr. iii.; tincture of sumbul ♏ xx., or the hypodermatic use of some strychnine salt in doses of gr. $\frac{1}{40}$ may be used. A somewhat novel recommendation is the employment of the continuous current in the areas of the vagi.

Some Cirrhoses of the Liver.—In this, the first of the Lumleian lectures, W. B. Cheadle discusses the symptoms of the affection and takes up some of the disputed points in its pathology and causation. The atrophic form is caused almost invariably by alcohol. Hypertrophic cirrhosis is not an earlier stage of the atrophic form, though Cheadle believes that in the latter there may be a stage of engorgement and congestive swelling before fibrotic contraction is fairly in progress. In eighteen cases examined the fibrosis was diffuse only once; in all the others it was coarse and multilobular. In hypertrophic cirrhosis, there is now no question that a fine fibrosis, monolobular or intralobular in arrangement, occurs in conjunction with hypertrophy due to alcohol; this diffuse fibrosis appears to be met with also in the cirrhosis attributed to malaria and in pure cardiac cirrhosis.

The Treatment of Rheumatism, its Prophylaxis and Cardiac Complications.—R. Douglas Powell does not believe that any germ thus far isolated has been proven to stand in a causative relation to the disease. Such proof may come later, but we do not have it now. He gives an enthusiastic indorsement of the use of the salicylates. In regard to the criticism sometimes made that under this plan of treatment cardiac complications are more frequent and relapses more to be feared than with the alkalies, Powell believes that Ewart has hit on the fallacy of these statistics when he remarks upon "the indirect risk that arises that we may be misled into overestimating its [salicylic acid] anti-rheumatic powers, and relax too early both treatment and diet."

A Case of Lymphatic Leukæmia.—The case was that of a man aged thirty-eight years, under the care of M. H. Spencer. The main features were the diminution in the number of ordinary leucocytes (fine granulated oxyphils), a great increase in the lymphocytes, and the presence of a number of nucleated red cells. Another feature of the case was the presence of an excessive enlargement of the liver accompanied by moderate ascites.

Death from Carbon-Dioxide Poisoning in a Brewery.—W. S. Thompson reports the case which occurred from a man's attempt to clean out a vat. A candle was taken into the vat, and as the man was found asphyxiated, the exact nature of the accident was unknown. Thompson declares that the candle is not a safe test, and that a watch should always be maintained at such times.

Suprapubic Cystotomy Painlessly Performed after the Hypodermic Injection of Eucaine.—T. V. Jackson did the operation on a man aged fifty years, using ♏ xl. of a seven-and-one-half-per-cent. solution of the muriate of the drug. The operation was absolutely not felt by the patient.

Extraordinary Case of the Loss of Both Eyes, One After the Other, from Similar Accidents.—A. Benthall records the case, the accident being that of "sticking the finger in the eye."

British Medical Journal, March 31, 1900.

Spleno-Myelogenous Leukæmia.—This case is reported by Thomas McCrae on account of the unusual features shown in the course of the disease. The patient came twice under observation with the typical condition of spleno-myelogenous leukæmia. On each occasion, under the use of arsenic, the leukæmic condition disappeared. The spleen became reduced to normal size, and the myelocytes disappeared from the blood. At these periods his health was good, and there was not any intercurrent affection present. The subsequent history of the case was unfortunately not obtained in detail. The patient went to California and died there some months later. His death was sudden, and was considered by his physician to be due to cerebral hemorrhage.

Piece of Amber in a Bronchus for Ten Weeks.—J. Frank Crombie reports this case, in which the patient swallowed a portion of the mouthpiece of his pipe. For the following two months the man continued at his work as coachman, and then had to take to bed. There were diminished expansion and dulness at the left base, and all over the left lung numerous sibilant rhonchi could be heard. Rest in bed was the only treatment that did any good. Finally, more than ten weeks after the accident the patient coughed up the foreign body without any trouble. It measured one and one-eighth inches long, one-half an inch broad, and five-sixteenths of an inch thick. The rhonchi, cough, and other symptoms disappeared at once.

The Condition of the Blood in Two Cases of Pernicious Anæmia.—Alfred C. Coles presents tables of the more important numerical alterations in the corpuscular elements of the blood in these two cases. They show very clearly the temporary improvement which may take place in this disease, and also the relapses and ultimate failure of all treatment. Each chart shows how difficult it would have been at certain stages to make a diagnosis from one examination, and also the impossibility of a definite prognosis for the immediate future, as both patients might at one time have been regarded as cured.

A Case of "Spurious Hermaphroditism."—J. Chalmers Brown reports this case. The conditions are summed up as follows: (1) absence of breasts; (2) absence of fat over trochanters; (3) absence of uterus and appendages unless a body in the right labium majus would be considered an ovary; (4) the presence of a body in the right labium majus, if considered a testicle. On the other hand, there were: (1) Feminine voice, hair arrangements, and "feelings"; (2) the presence of a clitoris, urethra, vagina, with hymen; (3) the pelvis had female dimensions; (4) the presence of a body in the right labium majus—an ovary.

Will-Making in Aphasic Paralysis.—James Edmunds reports the case of a single lady, sixty years of age, who was the subject of partial right-sided hemiplegia, with motor aphasia complete both as to speaking and writing. Instructions for the will were given by the patient by the selection of printed cards containing various directions, the patient selecting those expressing her desires. Death took place twenty-two days later. The will was probated, and the method devised for the ascertaining the wishes of the testatrix was approved by the court.

Anthrax of the Thigh Treated by Operation.—Thomas Sinclair reports this case, in which a healthy laborer, aged twenty-three years, while wheeling a barrow laden with bone manure was accidentally pricked in the inner side of the thigh by a splinter of wood on the barrow handle. Ten days after operation was performed, followed by a good recovery. The case is interesting because of the unusually clear history as to mode of infection and because of the bacteriological proofs.

Amputation without Anæsthesia.—Jasper Cargill reports this case, in which his patient, a black woman in Jamaica, while suffering the removal of a leg under chloroform, showed symptoms of heart failure. When told that the operation could not go on, she said: "Please cut it off, doctor; I can stand it without chloroform." After a brief consultation this was accordingly done, without a sign of resistance or even a groan from the patient.

Wiener klinische Wochenschrift, March 15 and 22, 1900.

Some Results of the Estimation of Blood Pressure in Cases of Mental Disease.—Alexander Pilcz, in reviewing his work in this line, remarks on the scarcity of the literature on the subject. This may be due to the fact that till recently there was no suitable instrument for conducting experiments. We now have Gärtner's tonometer. Pilcz made from nine hundred to nine hundred and fifty estimations among two hundred and forty patients. The forms of disease investigated were: general paralysis, hebephrenia, periodic mania, circular insanity, melancholia, and epilepsy. Normal blood pressure was estimated at from 105 to 130 mm. Hg. In paralytics the blood pressure varied with the age of the patient and the stage of the disease, falling lower with the progress of the latter, till in the terminal stage it reached from 50 to 80 mm. Hg. In hebephrenia the experiments were not very satisfactory. In the cases of periodic mania and circular insanity the blood pressure varied according to the special phase of the disease at the time of examination. During the melancholic stage the pressure was high, during the maniacal low. In patients affected with melancholia the pressure was high. The author was not able to make satisfactory experiments on epileptics during the convulsive attacks, but quotes Féré as saying that at the time of the convulsion blood pressure rises, while it falls in the interval between attacks.

Hæmatocolpos and Hæmatometra Resulting from Congenital Atresia of the Hymen.—E. Topp reports the case of a girl, thirteen years of age, who had never menstruated. On examination the labia majora were somewhat separated and between them there was seen bulging out a dark-red, smooth, fluctuating tumor. The nymphæ were invisible. The tumor was then palpated through the rectum and appeared to be quite extensive. The diagnosis was established. Under cocaine anæsthesia the tumor was incised and about one litre of dark brownish-red, thickish, odorless fluid was evacuated. At the same time the pain, which had been severe before the operation, ceased. The incised membrane was about 6 mm. thick, and was fibrous in consistency. The cavity was irrigated with weak sublimate solution, six stitches were taken, and an iodoform dressing was applied. Menstruation has been normally established since the operation, and is painless. It is interesting to note that an aunt of the patient had suffered from the same anomaly, but after operation married, and bore three children.

A Contribution to the Diagnosis of Diverticula of the Œsophagus.—Victor Blum, in discussing this subject, says that in some cases the etiology is so obscure that all available diagnostic measures must be applied in order to reach satisfactory conclusions. If, however, certain symptoms present themselves, such as the appearance of a swelling in the neck after the ingestion of food, the disappearance of the tumor after the regurgitation of the food, etc., then the diagnosis is very clear. The use of the Roentgen ray is often valuable. Another diagnostic aid is œsophagoscopy. The author reports the case of a man, sixty-six years of age, with characteristic symptoms of an œsophageal diverticulum. Through radiographic investigation it was discovered that there was a diverticulum of the posterior wall of the œsophagus, its position being between the fourth and seventh vertebræ. The shape was oblong. The etiology in this case was traced to traumatism of the pharynx about ten years before. The extirpation of the sac was strongly indicated in this case.

Cirrhosis of the Liver.—Richard Kretz believes that cirrhosis of the liver is a localized, recurrent, chronic degeneration process, with here and there regeneration of the parenchyma. The process begins in small foci of degeneration in the periphery of the acini; this is followed by regeneration which results in the rebuilding of the normal acini with a moderate change of form. The change especially affects the distribution of the capillaries, and consequently the nutrition of different parts of the parenchyma. Then areas of deeper-lying cells die, and the process proceeds to the complete destruction of acini in certain places. Secondarily the function and capacity for reproduction in the islands of parenchyma are destroyed. Finally, after the organ has been repeatedly destroyed and rebuilt in different areas, the destructive process preponderates and progressive atrophy supervenes till death occurs, unless the patient falls victim to a secondary or intercurrent process.

The So-Called Pericardiac Pseudo-Cirrhosis of the Liver (Fr. Pick).—Victor Eisenmenger writes of the disease named pericardiac pseudo-cirrhosis of the liver. Its essential characteristic is that clinically it presents a symptom complex which has a certain resemblance to that of cirrhosis, namely, a high grade of ascites, and either no or very slight œdema of the legs, while as the pathologico-anatomical foundation of the affection there exists a chronic adhesive pericarditis. After reviewing the subject in its different phases, he states that as a result of adhesive pericarditis there develops a comparatively high grade of ascites in the absence of œdema of the legs. If the pericarditis is latent, then the symptom complex has a certain likeness to cirrhosis of the liver. There is no one invariable anatomical cause for this affection, neither are its symptoms absolutely characteristic, and therefore this name should not be accepted.

Berliner klinische Wochenschrift, March 19, 1900.

Antipyresis.—Liebermeister gives an interesting review of the changing opinion regarding the treatment of fever during the past two hundred years. The older physicians believed that it was dangerous to reduce temperature too quickly, and so they most carefully avoided all cooling drinks and even fresh air in fever cases. Here and there through the literature of medicine are scattered references to the advantages to be derived from the generous use internally and externally of cold water, but the modern views of antipyresis really date from the work of Ernst Brand in Stettin, who in 1861 began that series of observations which have revolutionized the treatment of fevers. We now realize that the high temperature itself is dangerous regardless of its exciting cause, and the reaction from earlier enthusiastic views has simply been in the direction of learning how to employ antipyretic measures safely, so as to reduce the temperature without depressing the system in other directions.

Curative Results in Pulmonary Tuberculosis in the Charité Hospital during the Last Ten Years.—Schaper gives a comparative table of results obtained in the above institution in Berlin and those noted in the Institute for Infectious Diseases. In the former the mortality ranged from thirty-four to fifty-four per cent., the mortality curve showing with the exception of one or two years a progressive reduction; in the latter the percentage of deaths ran from thirty-three to twenty-seven, the average being twenty-seven per cent. There was not, however, the progressive lowering of the mortality curve as in the former case. He attributes the good results obtained in the Charité Hospital to various factors. We now have a much broader view of the essential problem of tuberculosis as to dietetic management and general hygiene. Moreover, the public is better educated as to the necessity of early intervention, and the patients come under observation at an earlier stage of the disease.

Tuberculin and the Early Diagnosis of Tuberculosis.—B. Fraenkel regards tuberculin as a definite and sensitive test for the disease, claiming that when local and general reaction appears we can surely predict the presence of the malady. He believes its diagnostic employment to be without danger. Such diagnostic tests should be conducted in a hospital, for it is necessary to take the temperature every three hours and to keep the patient under the closest observation. In pronounced cases in which the test fails, we have either an encapsulated focus which the injected material cannot penetrate, or else an advanced condition in which the process itself has caused the production of so much tuberculin that the little we inject can exert no effect. A few cases are on record in which reaction has ensued without the presence of the disease. The test finds a valuable field for employment in cases of chlorosis with cough and slight physical signs, which of themselves alone do not afford us ground for a positive diagnosis.

French Journals.

Actinomycosis.—A. Poncet and L. Bérard study the prevalence of human actinomycosis during the past two years in France. The cervico-facial region gives twenty-one cases, the pleural one, the cæcal and pericæcal two, the umbilical one, and the vesico-ano-rectal one. The yellow grains are not always to be found in fistulæ, etc., unless they are carefully sought in scrapings, etc. Iodide should always be given, though its curative effect cannot be guaranteed. An early diagnosis is essential, since later the disease may be beyond the resources of therapy. The clinical symptoms should precede and lead to the search for the yellow grain, which is the criterium in diagnosis.—*Le Bulletin Médical*, March 28, 1900.

Extra-Visceral Sarcomatosis.—L. Lapayre and M. Labbé present with illustrations an account of a young man of low physical and mental development, the subject of a congenital, hairy, pigmented mole covering the middle portion of the body like bathing trunks. Besides pigmented moles over the entire body there were numerous painful soft tumors, varying from the size of a pigeon's egg to that of the double fist. Three months after these tumors began to appear the man was dead. All viscera were found free, as well as the nervous and lymphatic systems. The case bears analogy to neurodermatosis in the evidences of race inferiority, but differs in absence of nerve involvement.—*La Presse Médicale*, March 2, 1900.

Note on a Case of Resection of the Stomach.—A. Ricard presented a patient whose stomach, the first portion of the duodenum, and a large portion of the pancreas had been resected for epithelioma. The operation lasted one hour and a quarter. The first day 1,750 gm. of serum were given, 500 in the veins. The patient was shown eleven months after operation, having gained fifty-two pounds, with a fresh, rosy color and signs of perfect health. Eight personal pylorectomies by the writer have recently been published, with seven recoveries. If done early, stomach cancer can be operated on as well as those of the rectum and uterus.—*Gazette des Hôpitaux*, March 22, 1900.

Shall Basiotripsy be Given Up?—Dr. Audebert concludes that an operation with all exposed to view is preferable to a blind procedure, and that the head should be held with tractors so that the borer does not slip at the moment of perforation. While a surgeon, deprived of the basiotribe, may in an urgent case diminish the size of the head piecemeal, the writer is convinced that basiotripsy, thanks to its absolute safety and uniformity of results, as well as to its simplicity, remains for the majority of cases the operation of choice, and that it cannot well be banished from obstetric practice.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, March 25, 1900.

Poisonous Fish.—J. Pellegrin leaves aside the injurious effects produced by inoculation and by wounds made with the attacking apparatus with which some fish are armed. These have recently been studied in the same journal by Coupin. He confines himself to poisonous effects due to the use of fish as nourishment. The poisons are either those inherent in the flesh, or due to substances taken in feeding from poisoned and polluted streams, toxic plants, or to diseases attacking the fish, often of microbic nature. All these factors are studied. — *La Médecine Moderne*, March 28, 1900.

Urinary Secretion in Eclampsia.—Paul Bar presents the results of his researches made with the view of determining the action of the kidneys in puerperal eclampsia, how oliguria appears, and fixing the place to be assigned to it. The most important point determined from the observations is that the functional trouble in the kidneys is secondary, and that good action of the kidneys does not prevent the fatal ending. —*Le Bulletin Médical*, March 28, 1900.

Black Tænias.—Charles Fritz finds a single instance of "negro tænia" in literature. He reports one instance personally observed in a practice of thirty years. He attributes the extremely black color to the patient's long use of bismuth during a chronic diarrhœa. With the expulsion of the worm the diarrhœa ceased.—*Le Bulletin Médical*, March 31, 1900.

American Journal of the Medical Sciences, April, 1900.

A Contribution to the Diagnosis of Diverticula in the Lower Part of the Œsophagus.—Franz A. R. Jung states that the reason why diverticula in the lower part of the œsophagus are usually overlooked is that this part of the tube is not generally examined in an ordinary autopsy. He reports two cases, and draws the following conclusions in relation to the differential diagnosis of diverticula: With dilatation, as well as with diverticula, there occur painful cardio-spasms (Kelly, Jung), as well as painless cases (Reitzenstein). In both vomiting occurs from the œsophagus, occasionally from the stomach. If food eaten one or two days before is vomited, while other food eaten in the mean time remains down, the case seems to be one of diverticulum. The swallowing sounds are abnormal in all cases of dilatation. If after emptying the œsophagus it is easy to enter the stomach, a diverticulum probably exists. The entrance of the diverticulum can easily be overlooked in œsophagoscopy. The value of gastrodiaphany varies with the individual case. X-rays show an enlargement of the œsophagus only.

The Value of Electrolytic Dilatation of the Eustachian Tubes in Chronic Tubal Catarrh and Chronic Catarrhal Otitis Media.—Arthur B. Duel concludes from experience gained in fifty cases that the pathological process in inflammatory conditions of the Eustachian tube and the tympanum is the same, *i.e.*, hyperæmia, followed by the exudation of round cells, which organize into new connective tissue, and subsequently atrophy. Chronic tubal catarrh and chronic catarrhal otitis media are different only in position, not in character. On account of its effect on hearing, obstruction of the Eustachian tube should be removed as rapidly as possible. The best method is electrolysis, for it is more rapid, more efficient, and its results are more permanent. In a word, all narrow tubes should be restored to their normal calibre, and when narrowing is due to an organized inflammatory exudate, electrolysis is the best method.

A Critical Summary of Recent Literature on the Localization, Diagnosis, Prognosis, and Treatment of Gonorrhœa in Women.—John G. Clark, after speaking of the different parts of the genital tract which may become affected, declares that the diagnosis of this affection in women is far more difficult than in men, chiefly because leucorrhœal discharge is more or less normal in the former, whereas in healthy men there is no urethral discharge. The most certain method of diagnosis is the demonstration of the gonococci in the secretions. In women, so far as the question of prognosis is concerned, the localization of the pathological process is the deciding feature. Different authorities vary in their opinions on this point. As to the treatment, absolute rest in the acute stages is one of the most important essentials. Silver salts, ichthyol, and immediate germicidal treatment in acute cases maintain an important place. As to the extent in operative treatment, authorities also differ.

Gumma of the Iris and Ciliary Body; Recovery with Normal Vision.—Charles A. Oliver reports this case of a man thirty-seven years old (a self-proclaimed syphilitic), who had lost the sight of the other eye six years previously. The interesting points in the case are: That the first eye affected probably suffered from a similar type of affection as that under consideration in the present instance; the recovery of the second eye with normal vision after three exacerbations; the endurance and positive value of larger doses of mercury; the comfort obtained by the local use of heat, mydriatics, and cyclopegics; the discharge of the gummous material into the ocular media, with the rapid disappearance of the mass; the temporary change of refraction from far-sightedness and astigmatism to near-sightedness and astigmatism; and the appearance and retention of the most curious ophthalmoscopic picture of chorio-retinal disturbance.

A Remarkable Case of Probable Thoracic Aneurism Presenting Intermittently through the Sternum.—Richard C. Cabot cites this case, of a woman aged forty-two years. The remarkable features are, that the aneurism eroded and perforated the sternum in two places without ever causing pain or any other pressure symptoms; that it presented externally as a tumor, and then disappeared under treatment by iodide of potassium, the skin rupturing without letting out any blood. This series of events was repeated several times in the course of seven years. Death occurred from the sudden bursting of the aneurism as the patient lifted a pitcher of water.

An Experiment in the Transmission of Syphilis to Calves.—Mazyck P. Ravenel used in this work two calves, and states that the results of the experiments, which were conducted with the greatest care, have been entirely confirmatory of the work of those observers who, like Neumann, have failed in all attempts to transmit syphilis to the lower animals, and who hold it to be impossible.

Pediatrics, March 15 and April 1, 1900.

Ophthalmia Neonatorum.—J. A. Day says it is difficult to overestimate the seriousness of this disease, which causes nearly thirty per cent. of all blindness. The eyes should be the parts to receive first attention from the physician who officiates at the birth. After cleansing them, a few drops of some mild antiseptic should be instilled, after which he should see that the eyes are not molested. If gonorrhœa is suspected, a few drops of a two-per-cent. silver solution should be dropped into each eye. Energetic treatment must be instituted in all cases of "inflamed eyes." The most important point is the early detection of beginning inflammation. and daily inspection should be the rule. The cardinal principle is to keep the eyes free from irritating discharges. Lid retractors should be avoided, as apt to cause injury. General rules of management are given.

Five Years' Experience in Private Practice with Diphtheritic Antitoxin Serum.—Frank W. Wright reports upon two hundred and sixty-eight cases, divided into four classes: (A) Environment the best and care most perfect; (B) good family care and sanitary conditions; (C) ordinary care; (D) poorest care and unsanitary surroundings. In class A were 33 cases and 6 deaths; in B, 60 cases and 7 deaths; in C, 95 cases and 17 deaths; in D, 80 cases and 29 deaths. Of those receiving antitoxin on the first day 12 died and 99 recovered; on the second day, 9 died and 58 recovered; on and after the third day, 37 died and 51 recovered. He concludes that the serum usually cures in favorable cases, and often in unfavorable ones. It prolongs life and lessens the severity; tends to prevent stenosis, and when intubation becomes necessary, it lessens the mortality. It prevents complications and sequelæ.

Cretinism.—Cristopher Graham reports a case of the sporadic variety. Thyroid treatment here finds a fruitful field of usefulness. It is commonly agreed that the condition is due to maldevelopment of the thyroid gland, its absence, atrophy, hypertrophy, perverted or abolished secretion; that it manifests itself either in early embryonic life, appears at birth or soon after, or is delayed until late childhood. The views of many writers are discussed. The capabilities of treatment are: (1) Removal of the myxœdematous condition; (2) quickening of physical development; (3) awakening of the intellect. Treatment must be continued through the entire life of the individual, otherwise relapses occur. The dose of thyroid varies for a child from gr. ss. to gr. i., gradually increased to gr. v. or more.

A Case of Mitral Regurgitation and Pulmonary Obstruction.—Augustus A. Eshner relates the history of a girl, aged eight years, who showed "nervousness" of the hands and feet, with shaking and weakness, for three months. At the apex a loud systolic murmur was heard transmitted to the axilla, and at the left base were a rough systolic murmur and an accentuated second sound. Treatment consisted in regulating the mode of life, digitalis, strophanthus, and iron, under which improvement took place. The writer considers the possibility of pressure exerted upon the pulmonary artery by the necessarily enlarged left auricle, though endocarditis of the pulmonary valves could not be wholly excluded.

Night Terrors.—Francis Huber reviews the opinions of Coutts. The term may be applied to a mild form of temporary mental disturbance, or the manifestations may be of central origin. In all instances there is an underlying neurotic or neuropathic state. The causes are very varied. No one remedy answers as a routine measure. The habits and life must be studied. Scolding should be interdicted. Tonics, ventilation, avoidance of stimulants, light evening meals, regulation of bowel function, are necessary. Adenoids or large tonsils should be removed. In neuropathic subjects, bromides, chloral, etc., render good service.

The Hygiene of Children's Sleeping-Apartments.—Joseph Byrne gives the results of daily observation in the habitations of working-people. The deficiency of pure air and light is generally deplorable, causing restlessness. The gas stove in such apartments is considered little short of murderous. Windowless middle rooms should be abolished. The best room should be the bedroom, and should be properly ventilated during the night. Bedrooms should not be swept, but mopped with a moist cloth. Stoves, as well as adenoids and nasal obstructions, are to be taken into account in treating diseases of infancy and childhood. Backward children should be protected by the physician.

Injuries of the Nerves due to Fracture.—Charles G. Cumston speaks of a girl aged seventeen years, who received a fracture just above the condyles of the humerus. After uniting the hand was practically powerless. Symptoms pointed to a lesion of the median nerve, due to callus or cicatrix. The nerve was exposed and a bony projection was chiselled away. No improvement took place for five weeks. After eleven weeks the functions were nearly perfect. An operation should be done as soon as the diagnosis is made, since much may be expected from early operation even in complicated cases.

A Fatal Case of Carbolic-Acid Poisoning in an Infant.—R. Abrahams relates an instance of death due to absorption by the skin in an infant seven days old. Convulsions came on five minutes after the fingers of a nurse, on which were a few drops of pure carbolic acid, came into contact with the skin. Symptoms of dyspnœa, shallow and labored respiration, cyanosis, rapid and feeble pulse continued for ten hours.

The Montreal Medical Journal, February, 1900.

Clinical Notes.—Stanley S. Cornell notes four cases. The first was that of a man aged sixty-five years, who contracted gonorrhœa. This was followed by arthritic and cardiac phenomena, and in about eight months he died. The second case was that of a man aged forty-seven years, the subject of chronic hip disease for forty-three years. He died during chloroform anæsthesia. This third case was that of a woman aged twenty-three years, suffering from tuberculous osteomyelitis of the terminal phalanx of the index finger succeeded by tuberculous invasion of the lungs. The primary cause was given as trauma. The fourth case was that of fatal hæmatemesis in a boy aged fifteen years, probably the result of perforation of a gastric ulcer.

Notes from Practice in the Argentine Republic.—F. G. Corbin reports three cases of mycosis narium—maggots in the nose. They are rare even in the semitropical climate of the Argentine. The first case was treated by a nasal douche of bichloride of mercury 1 : 2,000, followed by insufilations of calomel and iodoform in equal parts. The bichloride was later changed to carbolic acid 1 : 40, while camphorated naphthol was used as the paint. The second case being mild was treated with chloroform and gum camphor. The third case was treated much as was the first one noted. Corbin reports also two cases of diaphragmatic hernia, in both of which operation was refused.

Report upon Eighty-Nine Cases of Appendicitis Treated in the Royal Victoria Hospital, Montreal, during the Year Ending December 31, 1898.—E. L. Archibald states that many of these cases dated their first attack back to the age of ten or twenty years. They rarely came under observation during a first attack. There were fifty-five males and fifteen females in the series of seventy case reports. The "onset pain" is very variable both in character and degree. Chill is a rare event. Painful micturition as a sign of pelvic peritonitis was inconstant.

Medico-Legal Cases.—Georges Villeneuve describes two cases under the following headings: 1. Offense against Morals, Allegations of Irresponsibility on Account of Insanity and Epilepsy Set as a Defence, Disproved by Medical Examination; Condemnation. 2. Mere Mental Weakness Associated with an Entire Absence of Moral Sense; Two Previous Convictions Followed by Imprisonment in the Jail and in the Penitentiary; Another Arrest with Medical Examination and Subsequent Commitment to a Lunatic Asylum.

Two Cases of Auditory Peripheric Hallucinations.—E. P. Chagnon cites these two cases, in which it is necessary for the patient to undergo an impression either upon the sense of hearing or of touch to experience auditory hallucinations; no noises, no voices are heard. If everything is quiet they have no hallucination whatever.

On the Etiology of the Nausea and Vomiting of Pregnancy.—David James Evans advances the theory that the essential exciting cause of the nausea and vomiting of pregnancy is frequently the physiological contraction of the muscular fibres of the gravid uterus.

A Case of Rupture of the Rectum; Operation; Recovery.—Frank R. England notes this case of a girl aged twelve years. The child fell on a broom-handle which penetrated the anus to the extent of from twelve to fifteen inches.

The Journal of Tropical Medicine, March 15, 1900.

A Case of Ainhum.—A. B. Dalgetty reports a case of this peculiar disease, consisting in an encircling band, or furrow, of fibrinous tissue around the fifth toe of each foot. No cause for the condition can be ascertained. The patient is in good health, there is no sign of syphilis or leprosy, and the toes have not been injured in any way. Dr. Manson inclines to the view that the fibrotic change is analogous to keloid, and is started by an injury or irritation of some sort. He thinks it may be related to leprosy. Leprous parts are sometimes strangulated off by a fibrotic constriction without much ulceration, and ainhum ends by the toe being cast off.

The Endemic Centres of the Plague.—Frank G. Clemow says that in a region lying between 23° and 28° north latitude and between 100° and 104° east longitude plague has been endemic at least since 1860, possibly for one or more centuries. In 1894 it appeared for the first time in history in Canton and Hong Kong. In the year preceding this extension, which proved to be the commencement of an almost world-wide extension of the disease, plague was unusually active in its endemo-epidemic home in China. This extension was due to spread of infection, and not to any universal change simultaneously affecting the centres of the disease at distant parts of the earth's surface.

Notes on Beri-Beri in the Australian Pearling Fleet, 1883 to 1887.—T. H. Haynes reports forty-five deaths from this disease among five hundred and six men in voyages lasting altogether fifty-three months, and says that nothing has been reported to alter the opinion (1) that beri-beri is confined to a very great extent to rice-eating races, and with proper care will not develop in less than sixteen months; (2) that the substitution of a mixed diet of wheat flour, beans, potatoes, etc., to the exclusion of rice, mitigates, even if it does not prevent, the disease. Lime juice is not very useful, but beer is very beneficial.

Observations on the Epidemiology of Plague.—Frederick Pearse gives an account of the courses of three successive outbreaks of plague in Bombay, of one in Poona, and of one in Calcutta. Each outbreak in Bombay occupied about the same period of time. The average weekly mortality is between five and six hundred, and on this basis it is assumed that about twenty-two thousand lives have been lost each year from plague alone. The mortality is estimated at one in forty of the population; but in the last outbreak in Poona it was one in ten.

Five Cases of Terminal Dysentery.—W. J. Buchanan says that it appears certain that the occurrence of dysentery as a terminal symptom of many diseases of the tropics is a fact. He thinks, to use Sir William Gull's words, that it is "rather a mode of dying than a cause of death." The germ of dysentery is everywhere present in the tropics, and finds in dying persons a favorable soil to assert its virulence and hasten the end. The author reports five cases which illustrate his point.

Monatsschr. für Geburtsh. und Gynäk., March, 1900.

Contribution to the Etiology and Therapy of Genital Prolapsus.—A. Theilhaber states that the general cause of vaginal prolapse is from atrophy of the underlying fat and connective tissue. If prolapse of the anterior wall of the vagina continues for a long time, there follows prolapse of the uterus. Treatment for vaginal prolapse is plastic operation on the vagina; no operation on the uterus unless for rare primary prolapse of the uterus. For primary anterior vaginal prolapse, operation on the anterior wall; for posterior vaginal prolapse, excision; in complicating perineal ruptures, building up of the perineum.

Contribution to the Colpeurynter Question.—O. Kaufmann declares that in all those cases in which an early emptying of the uterus is indicated, but in which the conditions of the uterine wall do not allow this without danger, the use of the balloon is the safest and best procedure.

Sclerosis of the Uterine Arteries.—S. Cholmogoroff has observed in three cases primary lesions of the uterine arteries; this lesion was arteriosclerosis, not having an inflammatory process as a basis. In the first case the affection was part of a general process; in the other two, local.

A Laparotomy with Unusual Difficulty in Asepsis.—E. Meusel reports this case, in which he performed the second operation. The patient was a woman fifty years old, with a malignant proliferating cystoma, adenocystoma papilliferum.

A Case of Missed Labor with Myoma of the Uterus and Placenta Prævia.—A. Hartz believes the early death of the fœtus in this case was due to compression of the placenta and cord. There was no severe hemorrhage. The myoma was on the left side.

Retroversio-Flexion of the Partially Incarcerated Gravid Uterus; Urachus Fistula.—Unterberger cites a case of this kind, the cause of which he considers was traumatism in the first part of pregnancy.

Archives Provinciales de Chirurgie, March 1, 1900.

The Treatment of Tuberculosis of the Prostate.—H. Sarda considers this an affection which should sometimes be treated surgically, medical treatment by means of acids, silver nitrate, iodoform, etc., having given little satisfaction. The longitudinal prerectal perineal incision may be used in cases of perineal abscess, which, with the prostate, should be curetted. The transverse incision is preferable when there is neither abscess nor fistula. Should there be fistulæ, these should be followed up to reach the prostate. The longitudinal incision, as used by Roux or Delagénière or Guelliot, should be used in cases of prostatectomy. General treatment should not be neglected.

Burns from the X-Ray.—Ch. Février and G. Gross report two cases. To avoid such an accident, they advise the interposition of a sheet of aluminum connected with the ground, or else the ampulla should be placed at least 25 cm. away from the skin. Aluminum is transparent to the *x*-rays and retains all the electricity discharged by the tubes and conducts it to the ground. The discharges in the ampulla should be diminished in frequency, or a static machine may be used in connection with the ampulla. Individual susceptibility must be taken into account. Arthritic patients are especially susceptible.

A Grave Case of Anthrax of the Upper Lip.—By treatment with Marmorek's serum Alfred L. Dupraz obtained a cure in a case in which incision and curetting had been of no use. Albumin in the urine disappeared after use of the serum.

Annales de Médecine et Chirurgie, March 15, 1900.

The Prognostic Value of Lenticular Rose Spots. Exanthematic Form of Infantile Typhoid Fever.—Etienne Boulin concludes that in light forms of infantile typhoid fever the exanthem and enanthem are equally slight. In severe forms the cutaneous eruption and digestive troubles are equally developed. Among the forms of medium intensity there is the exanthematic form (Weill and Lesieur) characterized by (*a*) the importance of the lenticular rose spots; (*b*) the attenuation of intestinal symptoms; (*c*) the good prognosis. The abundance of rose spots is an unfavorable sign only if it coincides with the absence or reduction of digestive disturbances in cases of medium intensity.

The Essential Toxic Symptoms of Diphtheria.—John Biernacki says that the arterial pressure falls gradually; temperature falls equally. The urine gradually diminishes. In the cases he notes the fall of blood pressure has been slight in the beginning, then goes on progressively in this manner to the end. The symptoms that are considered essentially toxic have to a certain degree a constant character, and their development as well as their consecutive intensity is in intimate relation with the fall of blood pressure.

Cold Bathing in the Course of Typhoid Fever in Infants.—E. Ausset believes in the systematic bathing of infants suffering from typhoid fever, but considers the Brand method too severe in many cases. The favorable action on the nervous system and on the circulation is obtained frequently enough by baths at 26° or 28° C. When cases are not benefited at first by these milder baths, the writer gradually cools them down to the Brand temperature. He has never seen ill effects, even from the last method.

Lo Sperimentale, No. 1, 1900.

The Specific Serums.—Gino Galeotti says that Ehrlich's theory is that in order that any substance should be toxic to the organism it must possess the power to fix itself chemically upon the molecules which constitute the living protoplasm of the organism itself. This theory the author finds in complete harmony with the results of experimentation in regard to the action of serums and antitoxins.

Umbilical Tumors.—Teodoro Stori from his researches concludes, (1) that there may be developed upon the umbilical cicatrix an adenopapilloma, possessing the same histological characteristics as those originating from the intestinal tract—that is to say, developed from the remains of the omphalo-mesenteric duct; (2) that the omphalo-mesenteric duct may persist in the umbilicus and in the extra-peritoneal abdominal walls to an extent of about 5 cm. without any apparent connection with the intestines, presenting, however, marked involution extending to its deepest portion.

Morphological Study of the Thyroid Arteries.—Ferdinando Livini bases his work upon the examination of one hundred cadavers. He submits graphic representations of conditions observed, and describes first the types most frequently found.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

Preparations for a Change in Weather are being made in South Africa by both belligerent parties. The splendid summer is giving way to the rains that usher in the cold, and the cold when it comes is known by experience to be sometimes very severe. Already the hardships of the English army, a large proportion of whom have poor camping accommodations, have become considerably enhanced by the persistent wet, and a prolongation of the campaign will necessitate the supply of more suitable kits. Flannel shirts, warm underclothing, and thick uniforms are being rapidly manufactured in England for the forces, while articles of a similar nature are said to be reaching the Boers via Lourenço Marques. These and other preparations seem to show that, in spite of the sanguine forecasts of journalists, there is no immediate expectancy on either side of a declaration of peace. The Boers are still in possession of the north of Natal; their army is to a great extent intact, and their positions in their own country are strongly fortified, all of which things make it a little difficult to understand why their capitulation is so persistently looked for by a section of the British press. On the other hand, Great Britain is perfectly determined, before discussing the future of the Republics, to obtain an unqualified submission, and Lord Roberts' peaceful stay at Bloemfontein is only the prelude to an organized attack upon the Transvaal territory.

The Condition of Mafeking.—I am still unable to report the relief of the Mafeking garrison, but since my last communication several telegrams have come through from Colonel Baden-Powell to Cape Town showing that he is still able "to keep his end up." Undoubtedly the relief columns have a difficult task before them, as they have to maintain intact lines of communication of immense length. To gallop into Mafeking without bringing stores and without opening and keeping open a way by which stores might be brought, would be to insure the immediate downfall of the town by starvation and disease. The town remains fairly healthy, and the food supply should last some time yet. The number of the garrison is not large. I have seen it given as 10,000. This figure is too high. It is the figure of one of the big contractors who supplied stores in view of a possible siege, and includes both those who have since died and those who made their escape from the town in the last day or two. It will probably be found that Colonel Baden-Powell has under his care rather under 2,000 whites and about double as many blacks—that is, including civilians of both sexes, children, and troops. The contract to supply Colonel Hore's forces specified as soldiers four hundred and forty Europeans and one hundred and ten natives, and specified also four hundred and forty horses and seventy-three mules, and the outside duration of the siege was estimated at three months. The investment has now lasted over five months, but the contractor sent a much greater supply of stores upon his own well-inspired initiative, and if the town is saved his action will have mainly saved it.

The Herbert Hospital, at Woolwich, just outside London, which Queen Victoria has recently visited, was built at the instance of Mr. Sydney Herbert, afterward Lord Herbert of Lea, who was Secretary of State for War during the Crimean war. It was designed by the late Sir Douglas Galton, and within its walls Sir Douglas' famous cousin, Miss Florence Nightingale, carried out the views on hygienic nursing which have made her name famous throughout the world. The Herbert Hospital, like the other big service hospital at Netley, is crowded with sick and wounded who have returned from the war.

Professional Jealousy among the Boer Medical Men.—I have already referred to the very cold welcome extended by the Boers to the medical men and ambulance establishments which, with the kindliest motives, have gone to the Transvaal. This attitude was at first explained by the fact that the Boers, having obtained from the various foreign powers to whom appeal has been made, much verbal sympathy but no substantial help, feel a deep distrust of Europeans; but it seems likely that professional jealousy has played a part. Major F. A. B. Daly, of the Royal Army Medical Corps, who was captured by the Boers after the battle of Dundee, and who has since regained his freedom, says that during his captivity he helped to alleviate the sufferings of the wounded Boers, with the result that he excited so much jealous feeling among the Boer doctors that it was decided to send him back to his own troops. Thus was virtue rewarded.

The Death of General Joubert.—Petrus Joubert—"Slim Piet"—the commander-in-chief of the Boer army, died in Pretoria on March 27th from intestinal obstruction and peritonitis. The diagnosis is conjectural, but it is known that he has been suffering from symptoms of the condition for some time, and it has certainly required the greatest fortitude on his part to remain in the field. In him the Boers have lost a great general, and the British a fine foe. He was a

Frenchman by birth, but had lived forty-five years in Dutch South Africa, and had held high civilian office in the Transvaal before being called to his military position. He is known to have been opposed to going to war with England, although his aspirations for an independent Dutch Republic, free from British trammels, were every whit as real as those of President Kruger. But Joubert, though a good soldier, believed implicitly in diplomacy, and earned his nickname by his skill in conducting negotiations. He was averse to losing all chances of achieving Dutch aims peacefully, a position which he knew would follow if his countrymen made an armed invasion of British territory. But his advice was overruled, and when he found that he had to fight, he fought with great strategic skill. His invasion of Natal was an admirably planned affair, and, in spite of Sir George White's pluck and resource, the Boers might have reached Pietermaritzburg, and even Durban, had it not been for the grand work of the British naval brigade, who were present at Ladysmith more or less by accident.

The Boer Ambulance Wagons, which fell into the hands of Lord Roberts during his march into Bloemfontein, show well that the Republics have made very good preparation for the care of their wounded. I suggested that when we knew more about it we should probably find this to be the case, for there never seemed any grounds for believing that an army so well provided with all military *impedimenta* had no proper arrangements for the succor of the wounded. Over and over again this has been stated, but never upon trustworthy information. As a matter of fact, the Boer ambulance wagons turned out to be very comfortable vehicles. There is no uniformity of pattern about them; on the contrary, covered vehicles of every shape are used, the only external thing in common being the flying of the Red Cross. But all the ambulances are well furnished within with mattresses, and clearly only conveyances with good springs have been selected. Also the wounded are expected to require transport in a lying-down condition, and the ambulances are prepared with this in view. The British ambulance wagons are very neat, clean, and uniform in pattern; but a large proportion of the wounded have to be removed in a sitting posture, and the build of wagon is one that does not run lightly. On the whole it is probable that the Boer wounded suffer less than the British wounded during transport along the abominably rough roads of South Africa.

OUR LONDON LETTER.

(From our Special Correspondent.)

LECTURES AT THE COLLEGES—BROWN INSTITUTION—LETTSOMIAN LECTURES AT THE MEDICAL SOCIETY—SURGERY OF THE SPINE—MIDWIVES BILL.

LONDON, March 30, 1900.

WE are in the lecture season. Those who have so often inveighed against overlecturing students might very well direct some of their criticisms to the provisions made for practitioners. Both the royal colleges give courses of lectures on various subjects. Some of the societies have lectureships, and there are other fixtures each season. Of late, too, the Post-Graduate School has extended the system. If he tried to attend many the practitioner would have little time left to digest all he heard. But he knows better, and most of the courses fail to attract him. I have been at lectures by distinguished men when the audience could be counted on the fingers. Still the older established courses have an imposing history and may usually be heard with profit.

The Arris and Gale lectures at the College of Surgeons were delivered last month by Mr. B. G. A. Moynihan, of Leeds, who devoted them to the anatomy and pathology of the rarer forms of hernia. The Hunterian course was entrusted to Mr. Mayo Robson, who lectured on the surgery of the stomach. He produced statistics gathered from various sources and gave the results of his own operations. He takes a hopeful view of this branch of practice and thinks its success should be as great as in that of the gall bladder. He appeals to the medical side for earlier diagnosis and earlier consultation with the surgeon.

At the College of Physicians the Milroy lectures have been given by Dr. F. J. Waldo, one of our leading medical officers of health. He took for his subject epidemic diarrhœa, and suggested that the dust of towns might be the purveyor of the infecting microbe. Such dust being always polluted with horse-dung, this might be the chief agent of distribution. If the idea only leads people to be more careful to preserve milk and other foods from dust it will be a benefit to many.

The Goulstonian lectures have just been concluded. They were given by Dr. Horton Smith, who discoursed on typhoid and its bacillus. I may name one point he enforced, viz., we cannot regard it as an intestinal disease. It is more like a modified septicæmia, for in all cases the bacilli pass into the blood and thence to the various organs, and the symptoms are referable to the poisons there produced, except those of the intestine. It is modified in that there is in nearly all cases the definite local primary disease whence secondary dissemination of the microbe takes place.

The Lumleian lectures were begun yesterday by Dr. Cheadle. The subject is cirrhosis of the liver.

The Lettsomian lectures of the Medical Society of London have been delivered by Sir William M. Banks. Now he is one of the advanced surgeons and always expresses himself with clearness. His style is easy and forcible, often picturesque, and everything he writes is worth reading. He took as his subject cancer of the breast, and gave a synopsis of what is known about it from his own point of view. His impressions after thirty-three years of surgical work must be of value, although, as he remarked, statisticians hold such evidence in contempt. It is often said figures cannot lie, but, said Sir William, "it has long been painfully manifest that nothing can be more lying and delusive than statistics if not properly used." As a result of improper use of medical statistics he found that "many errors have been long handed down from book to book until some disagreeable doubter has arisen who has exposed them." Further he observed that erroneous conclusions may be drawn from correct figures. "If any one wants to know how statistics may be manipulated and applied, let him consult the literature of the anti-contagious diseases, anti-vivisectionist, and anti-vaccinationist propaganda—all prepared by persons of the most superior virtue." The questions of increased prevalence, local distribution, cause, heredity, and traumatism were then looked at. Diagnosis occupied the whole of one of these interesting lectures. "There are some delusions about cancer of the breast to which almost the entire public still give credit, and, I regret to say, not a few medical men. They are partly the result of text-book statements not properly explained, and partly the result of popular tradition. They are difficult to eradicate, because there is just that small amount of truth in them which makes it possible to argue about them." And with this preface the lecturer proceeded to examine a number of these errors.

Prof. Rose Bradford, physician to University College Hospital, is also superintendent of the Brown Institution, and delivers five lectures a year at the London University, as required by Mr. Brown's will. The work of the institution consists of three departments: First, there is the animal hospital under the care of veterinary officers, by whom many animals are continually treated for the diseases to which they are liable. Then there is the routine investigation of cases of suspected rabies in the laboratory of the institution; and, thirdly, there is the work of research concerning the diseases of man and animals, conducted in the laboratory by the professor and others. This year Dr. Bradford opened his course with two lectures on rabies, the other three being devoted to the tsetse-fly disease of South Africa. In the last five years between three hundred and four hundred cases of suspected rabies have been investigated at the Brown Institution, and some useful statistics accumulated. Dr. Bradford prefers the term rabies for the disease in man as well as in animals, hydrophobia being to a great extent a misnomer. Having noted that the disease was mentioned by Aristotle and described by Celsus, he briefly followed its history down to Pasteur, whose work was of course carefully described. This concluded the first lecture; the second dealt with the diagnosis of rabies in both man and animals.

In these days of daring surgery it is difficult to feel more than slight surprise at desperate attempts at operation. The spine is not a very promising part for interference, but modern surgery has met with some successes in that region. A case was related at the Clinical Society last Friday in which an attempt was made to remove a dermoid tumor growing in the spinal canal and pressing on the cord. The patient was a man aged twenty-six years, suffering from chronic Hodgkin's disease. Symptoms came on indicating a collection of fluid or some growth, irritating the second dorsal nerve and compressing the cord below it. This diagnosis having been arrived at, and there being no evidence of malignancy or of syphilis, laminectomy was performed, the second, third, and fourth dorsal arches being removed, when a gray tumor was exposed on the outer surface of the dura mater, reaching out of sight above and below. Pieces of the growth were snipped away and the patient rallied. Pulse and temperature fell to normal from 120 and 101° F., and great improvement followed, but as the relief was far from complete a second attempt to remove the tumor was made. The first, fifth, and sixth dorsal laminæ were accordingly removed, but no limit could be seen to the growth. The patient died eight hours afterward.

Sir D. Powell, president, remarked that the case was interesting as bearing on the question how far interference was justifiable in such cases.

After this there was some discussion on the reduction of the deformity of Pott's disease by manual rectification. You will remember, perhaps, that I told you at the time of the cases brought before the society in 1897 by Messrs. R. Jones and Tubby. Since then they have had many cases, bringing the total to ninety-nine, of which they now gave their report. They showed some of the cases of the first series, that the fellows might judge of their results. They advise the plan only when the spine is yielding in young, strong children free from abscess or tubercle. They insist on the necessity of unremitting personal care and mention numerous contraindications, and say fresh air is an all-important adjuvant. Altogether they seemed less enthusiastic than before. The speakers who followed gave little encouragement, seeming to consider the correction of the deformity more apparent than real. The estimate of the usual mortality of Pott's disease, placed by the authors at twenty-five per cent., was challenged by Mr. Marsh, who put it at five or six per cent., and said paraplegia was recovered from under other treatment.

Eventually the meeting agreed to appoint a committee to report on the subject, the terms of reference to be drafted by the council.

The advocates of the midwives bill have managed to rush it through the standing committee, to which it was referred without material change. In a couple of sittings that committee finished its work, and the bill will soon come on in the report stage. The difficulty of defeating it is thus necessarily increased, and only the most strenuous efforts will avail to change it. But where are these strenuous efforts to hail from? The corporations and societies have done nothing. Apathy seems to have fallen on all but a few who have pointed out the dangers to the profession and the public, but have failed so far to arouse either. Sir George Pilkington, Mr. T. P. O'Connor, Mr. Lloyd-George, and Dr. Commins deserve credit for the efforts they made to amend several clauses, but the opposition was too strong. Mr. Atherley-Jones, whose name you may recall as having on other occasions made himself ridiculous, objected to midwives being subjected to restrictive rules by the General Medical Council, which he spoke of as "a body of rival practitioners," and he quite let the cat out of the bag as to the wish of the promoters of the bill to set up a distinct class of practitioners—a wish they had up to this period absolutely repudiated. The country practitioner was also sneered at as if his five years' curriculum scarcely entitled him to a position equal to that proposed for the Mrs. Gamps to be registered on account of their present experience, or their successors who are to be trained for three whole months! The society ladies who are working for the bill on behalf of "poor women in their trouble" will probably take care not to engage the new midwives in their own time of trouble.

A meeting of the constituents of the Southeastern divisions of London is called for Monday to impress on their parliamentary representatives the dangers of the threatened legislation.

PUBLIC SERVICE AGAINST PRIVATE WORK.

To the Editor of the Medical Record.

Sir: As indicating how the public mind has been and still is being educated, the incidents in an accident case are interesting.

While walking down Broadway on March 28, 1900, I saw a man start to run with a small boy in his arms, followed by several persons, and just after he passed me I heard him asking of those near him the shortest way to the New York Hospital.

Only a few doors below on the corner is a cigar store—about it was a crowd, some also in the store. Thinking others might have been injured besides the boy, I crowded my way in and offered my services to the policemen (there were two).

They told me no one was hurt there, and said the boy had been run down by a truck. They were trying to induce the woman in charge of the cigar store to make a charge against the truck driver, which she was declining to do. She was rapidly becoming hysterical because of the injury to the boy—how serious she did not know—and because of the crowd. I advised the policemen to disperse the crowd, lest they have another case; assured the woman that the boy seemed much more frightened than hurt, from what little could be learned by mere observation, and went on about my business; which having completed, I walked up Broadway and again met the cigar man with the boy. This time the boy was walking; he looked a trifle pale; he had one arm out of his sleeve and supported in some kind of sling.

The man informed me that at the New York Hospital they had told him the boy was little injured, and then said: "You know he was only knocked over by the truck."

Why should this man's first impulse be to run off to the hospital, six or seven blocks, when he thought his boy injured, and pass, in doing so, several doctors' offices by any possible route? Again, why should the police press upon the boy's mother—if mother she was—in the cigar store the necessity of her making a charge against the driver of the truck, when she stoutly refused to do so? Was it because they were afraid of having some irresponsible persons attack them for not doing their duty? They urge a woman after she has said: "I want nothing of this driver or his people."

Surely there is no hope of financial reward in this case, and to my mind is only another evidence of the direction in which we are drifting, *i.e.*, toward having everything done by public officials or public institutions.

Is it not wise to pause and ask ourselves the question: Is there no way to check this tendency? Would not the people who give so much time to worrying officials do well to institute measures, if possible, by which people should do more for themselves, and ask less of the officials and of institutions?

Put every one on his honor, officials, citizens, and all, leaving paternalism on the part of the government as much as possible in the rear. At our present pace it will not be long before there is none left besides the official and the dependent classes.

WICKES WASHBURN, M.D.

March 31, 1900.

LEPROSY LEGISLATION.

To the Editor of the Medical Record.

SIR: Shortly after the appearance of my article on leprosy in your journal of January 27th last, Dr. A. S. Ashmead, of New York, who appears to be a bibliographical leprologist (a gatherer of facts in regard to the subject of leprosy), sent to some eastern newspapers an article making substantially the same recommendations in regard to national legislation that I made in my contribution to the MEDICAL RECORD. Since the appearance of this article, it has been extensively copied east and west, in literary, medical, and daily publications, in several instances misquoted and misrepresented, especially by political papers that have tried to arouse partisan prejudice. I have been forced (much as I dislike discussing medical matters in the newspapers) to deny some of these statements attributed to me. For one thing, it shows where the MEDICAL RECORD goes, and, by the way, *Current Literature* for March credits my article to another medical journal.

My contribution was written not to alarm the general public, but to call the attention of the profession, and, through it, the attention of our legislators, to the fact that we have no protection in this country against a spreading disease. I wished to emphasize the need of national and State legislation upon the matter; of wise, comprehensive, prompt measures that shall prevent any considerable spread of leprosy on the mainland. We want such legislation now, not because we have annexed Hawaii, Puerto Rico, and the Philippines, and are in closer relations with the West Indies and the Orient, or because there is a sudden, emergent need to act, but for the reason that the obligation rests urgently upon us, because the obligation is long past due. In a legislative way, we have left undone the things we ought to have done, and therefore should now do the things that ought to be done.

I am glad to see that Dr. Prince A. Morrow, in his article on leprosy in the eighteenth volume of the "Twentieth Century Practice," just out, has seen fit to express his belief that leprosy may become a current disease, and to recommend national legislation in order to control the disorder. A year ago I made the same recommendations, and, with the permission of the MEDICAL RECORD and of some other medical journals, I shortly shall have reproduced in book form these same suggestions. Referring again to Dr. Ashmead's article, I think that his figures are misleading, if they are not entirely incorrect. He places the number of lepers in Hawaii at four thousand, which is an overestimate by twenty-nine hundred. As for our eastern islands, with eight thousand lepers on one island, I may say that no one at present has any means of knowing how many lepers there are either in the Philippines or in Cuba. Had annexation changed the physical status of the islands, these uncertainties might alarm us; but the truth is, we are as far away from our annexed territory as we were before the war. However, if the annexation of these islands does not materially increase the danger here, it may serve the purpose of rousing our government to action that should have been taken years ago; even before we had lepers of our own.

That we need not be hysterical about the matter is shown by the fact that New Brunswick has had its lazarettos many years without any alarming spread of leprosy in the locality. The danger lies in our not having any efficient provision against the spread of leprosy in our midst from existing, permanent foci in several of our States, and from the fact that isolated cases are going here and there among us with more personal liberty than the healthy negro is enjoying in the South to-day. Our general quarantine laws are not specific enough to affect this disease, and any of us are liable at any moment to be exposed to leprosy in its worst forms.

Besides, without going to lands across the sea, we are exposed to the lepers of Mexico and Central America—contiguous States. I would recommend that a commission be appointed to inquire into leprosy in this country; that this commission be empowered to visit Hawaii and other leper-infected countries, for the purpose of studying their laws of segregation, and their methods of dealing legally and therapeutically with the disease; that the report and recommendations of this commission be acted upon without delay. Such a course would stamp out a disease that may yet spread to all parts of the United States, and become as general as it was in Europe at one time.

The national medical officers we have at the present time are particularly well qualified to handle this matter, and our learned surgeon-general would no doubt gladly use his abilities with the special powers granted him, to provide some safeguard against the spread of leprosy.

E. S. GOODHUE, M.D.

LOS ANGELES, CAL., March 23, 1900.

Decapitation with the Karl Braun Key-Hook.—Karl A. Herzfeld gives a detailed account of the method of using the Karl Braun key-hook, and states that it may be used to perform embryotomy as well as decapitation, eventration, thoracotomy, etc. Its application is indicated in the wedged shoulder position, if the child is dead and version is impossible or contraindicated, as well on account of the wedging of the child as the stretching of the lower uterine segment. The key-hook is formed like the small upper end of Smillie's instrument, only it has a somewhat more parabolic curve, and at its lower end a knob—a knobbed hook—while the lower end of the metal rod is inscribed in a cross handle. In the three Vienna clinics (Gustav Braun, Chrobak, Schauta) the Karl Braun hook has been used for decapitation, always with the best results.—*Centralblatt für Gynäkologie*, March 17, 1900.

Reviews and Notices.

A Compend on Diseases of the Eye and Refraction, including Treatment and Surgery. By George M. Gould, A.M., M.D., formerly Ophthalmologist to the Philadelphia Hospital, and Walter L. Pyle, A.M., M.D., Assistant Surgeon to Wills Eye Hospital. Philadelphia: P. Blakiston's Son & Co. 1899.

This is one of a series of quiz-compends, and is as good as most books of the kind.

The Trained Nurses' Directory. Compend of Names Carefully Selected by Prominent Physicians and Surgeons of New York and Vicinity from their Private Lists. Compiled and Edited by M. Louise Longeway, Graduate of the New York Training-School, Bellevue Hospital. Sixth edition, New York. 1899.

This is a new edition of this useful publication. The work is designed for the use of physicians and families who may need the services of graduate nurses, who have been specially selected and recommended by leading physicians and surgeons as having had requisite hospital training and subsequent practice in private duty. The names are alphabetically arranged, giving address, telephone number, school, year of graduation, and the special cases taken by the graduates doing private duty in New York, Brooklyn, Albany, Orange, N. J.; Pittsfield, Mass.; Hartford, and New Haven, Conn., and the towns adjoining those cities.

Materia Medica and Therapeutics. An Introduction to the Rational Treatment of Disease. By T. Mitchell Bruce, M.A., M.D., Fellow of the Royal College of Physicians of London; Physician and Lecturer on Medicine, Charing Cross Hospital; Consulting Physician to the Hospital for Consumption, Brompton; Examiner in Medicine in the University of Cambridge; formerly Examiner in Materia Medica in the University of London and the Victoria University, and Examiner in Medicine on an Examining-Board in England. Philadelphia: Lea Brothers & Co.

This is a handy duodecimo volume containing all the essentials of materia medica in compact form. The author attaches importance to the plan which he has adopted in the description of special therapeutics, of tracing the physiological actions and uses of the different drugs in their passage through the body, from their first contact with it locally until they are eliminated in the secretions. The work is divided into three parts, dealing respectively with the inorganic materia medica, the organic materia medica, and general therapeutics. The third section is particularly to be commended, though those on the materia medica will be found very useful for reference.

Bacteriology in Medicine and Surgery. A Practical Manual for Physicians, Health Officers, and Students. By William H. Park, M.D., Associate Professor of Bacteriology and Hygiene in the University and Bellevue Hospital Medical College, New York. In one 12mo volume of 688 pages, with 87 illustrations in black and colors, and two full-page colored plates. 1899.

Dr. Park's well-known studies in the laboratories of the New York City board of health especially fit him to write with authority upon the subject of bacteriology and hygiene. In this volume we have not only a practical exposition of all laboratory methods such as health departments should employ, but also the simpler methods such as the active practitioner can use at home. The value of the laboratory diagnosis is also discussed in full. The subject of hygiene has been particularly well treated in so far as relates to the methods of disinfection and purification of water supply, and the book can be recommended as one which meets every requirement of the health officer as well as of the practising physician. An appendix describing the more common micro-organisms not bacteria, such as the streptothrix group, plasmodium malariæ, amœba coli, etc., is of additional interest, while an index of infectious diseases with the bacteria found in each affords a ready reference which is helpful to a busy man. The language throughout is exceptionally clear and crisp, the details of laboratory technique are wonderfully complete, and the illustrations are excellent.

Children, Acid and Alkaline. Health, the Golden Mean; the Law of Diet Selection, Contraria; the Therapeutic Law, Similia. By Thomas C. Duncan, M.D., formerly Professor of Diseases of Children, Hahnemann Medical College and Chicago Homœopathic Medical College. Philadelphia: Boericke & Tafel. 1900.

The author of these one hundred and forty-eight pages divides children into normal, acid, and alkaline. Hahnemann had already discovered the chemical tendency. Contraria is assigned a permanent place in diet selection. Other writers are freely quoted, and the aim of the little work is to aid in developing healthier, happier humanity.

Christian Science: An Exposition of Mrs. Eddy's Wonderful Discovery, including its Legal Aspects. A Plea for Children and Other Helpless Sick. By William A. Purrington, Lecturer in the University and Bellevue Hospital Medical College upon Law in relation to Medical Practice; one of the authors of "A System of Legal Medicine." New York: E. B. Treat Company. 1900.

This is a collection of the author's writings upon the subject of Christian science as originally published in the *North American Review*, the Medical Record, and the New York *Sun*. Taken together they form a strong arraignment of the Eddy cult and the crimes perpetrated in the doubly sacred name which it has adopted.

Herman Ludwig Ferdinand von Helmholtz. By John Gray McKendrick, Professor of Physiology in the University of Glasgow. New York: Longmans, Green & Co. 1899.

Undoubtedly Helmholtz possessed one of the most brilliant minds of the present century, and the study of such a man's qualities, and the powers which secured for him such a high place among the investigators of the world, must be a pleasure and a profit to all lovers of nature and of nature's noblest works. The biographer has had a delicate and indeed in many particulars difficult task to perform in looking into the working of so creative a mind, and following up the inquiries pursued by this scientist. Little has been known and less published about the private life and personality of Helmholtz, and the present work, though small, gives an excellent and most entertaining account of the philosopher from the earliest to the closing years of his life.

The Nervous System of the Child, its Growth and Health in Education. By Francis Warner, Physician to and Lecturer at the London Hospital, etc. New York: The Macmillan Company. 1900.

This is a work addressed to all those who work for the welfare and education of children and to those seeking knowledge as to the workings of the youthful mind and body. Scientific methods of work in accomplishing the ends desired are pointed out. The study of the nervous system has much to do with questions of training as with those of health, and the whole question of management is discussed from the school rather than from the family standpoint. The needs of teachers have been kept in the foreground, and still questions of hygiene as it concerns boarding-schools have not been overlooked. The feature of the work would appear to be an indication, by a medical man, of the aids which medical science may render those who have to do with the bringing up of children.

Cheloid of the Lobule of the Ear.—Marcel Natier reports an interesting case of this nature occurring in a woman, aged forty-one years, and belonging to the better class. The exact cause of the mass could not be determined, as it dated back to the early childhood of the patient. Both ears were affected, and there were similar lesions in different parts of the body. Attention is called to the rarity of these formations at this site in the white race, though they are more common in the black races. Reference is made to the literature of other cases, and a résumé is given of the different modes of treatment. None of the latter seems to be very satisfactory so far as concerns the permanent removal of the growths.—*La Parole*, February, 1900.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 14, 1900.

EUGENE HODENPYL, M.D., PRESIDENT.

A Case of Malaria following Wound Infection.—DR. F. M. JEFFRIES reported this case. A surgeon of this city who had never had malaria, and who had been in the city up to July 15, 1899, had then gone to Seabright, and had remained there from July 15th to 20th. While there he had driven around during the daytime, but had remained indoors at night. This neighborhood was not considered a particularly malarious one. From July 25th to September 15th he had been in the northern part of New Hampshire, where malaria is entirely unknown. He had returned to this city on September 15th, and on September 18th had performed a vaginal hysterectomy on a patient who, the next day, had had a distinct and marked malarial chill. This patient was from North Carolina, and had previously had frequent attacks of malaria. The next two days she had had chills, and as she had been given quinine on the second day there had been no further chills. At the time of the chill examination had shown no evidence of infection. During the operation referred to the surgeon had pricked his finger several times. On October 4th, or sixteen days after the operation, the surgeon had had his first chill. This had been followed by several others, each attack lasting for four or five days. On November 24th, or just prior to one of the paroxysms, the speaker had examined his blood and had found the plasmodium malariæ in great abundance. It was of the variety known as the æstivo-autumnal—a variety not commonly met with in this locality except in those who have had it previous to coming here. The evidence presented by this history certainly led one at least to suspect very strongly that the surgeon had become infected with malaria by wound infection. Specimens of the blood were exhibited under the microscope.

A Case of Advanced Tuberculous Coxitis.—Dr. Jeffries showed an extreme case of tuberculosis of the hip. The specimen had been removed from a girl aged ten years. The acetabulum was almost wanting, and the head and neck of the femur were entirely gone. Pus had burrowed as far back as the sacrum. The right hip was normal. In the left knee joint was found a nail such as is used in holding together the bones after excision of this joint, but there was no history of such an operation having been done in the hospital in which she had died. At the autopsy the upper right apex of the lung contained a small tuberculous nodule. The liver and spleen were enlarged and amyloid. The bladder showed a few tuberculous ulcers. The left kidney was fatty and tuberculous in its upper half. The uterus presented a tuberculous endometritis, and there was also a tuberculous salpingitis. The mesenteric glands were enlarged throughout.

DR. CARLIN PHILIPS asked whether the woman upon whom the operation of vaginal hysterectomy had been done had originally had the æstivo-autumnal variety of malaria.

DR. JEFFRIES replied that this patient had come from a region in which this variety was common, but there had been no opportunity of determining this point positively.

Two Cases of Perforation of Tuberculous Bronchial Lymph Nodes into the Trachea.—DR. F. S. MATHEWS presented the first of these cases. The specimens had been taken from a child, aged four years, who had been in the St. Mary's Hospital for Children for several months under treatment for tuberculous disease of the knee. On the night of January 19th the child, while apparently in his usual health, had suddenly begun to cough, and had soon choked to death. At the autopsy, made the next day, there had been found on the right side an opening from which pus was oozing. This connected with the abscess cavity. The trachea and right bronchus contained a considerable quantity of pus. Tubercle bacilli were found in this pus, and also in the mediastinal glands. No other tuberculous lesions had been found in the thoracic or abdominal cavities.

DR. M. NICOLL, JR., presented the history of a second case. The specimens had been taken from a child one year and a half old, who had been in the out-patient department of the New York Foundling Hospital under treatment for bronchitis for about one week. The child had then been taken into the hospital because of the urgent dyspnœa and cyanosis present. Expiration was more difficul tthan inspiration. The child had been immediately intubated, but without relief, and death had taken place in a few minutes. When the thorax was opened the left lung had been found over-inflated, and in a condition of very acute emphysema. On cutting through the left primary bronchus a large plug of mucus had forcibly escaped, and the lungs had then immediately collapsed. In the trachea, near the origin of the right primary bronchus, was an oval opening communicating with a cavity formed by the breaking down of a large tuberculous gland. The bronchus leading to the right lower lobe ended in a mass of tuberculous consolidation. The over-distention of the left lung was apparently due to the valve-like action of the inspired mucus plug; the power of expiration was not sufficiently strong to expel the air taken in at each inspiration.

A Case of Membranous Laryngitis Complicating Typhoid Fever.—DR. ALEXANDER LAMBERT presented the larynx from a person who had died of gangrenous laryngitis. The man was an alcoholic subject who had entered the hospital with a temperature of 105° F., marked dyspnœa, severe cough, and laryngitis. The leucocytes had been reported as being only five thousand, and on that basis a diagnosis of typhoid fever had been made. The next day the spleen had become palpable, and a profuse typhoid eruption had appeared. Toward the end of the third week the temperature had fallen very decidedly, and the man had shown every evidence of improvement. About this time the laryngitis had become much more severe. The fauces were red, and in the back of the pharynx was a slight grayish deposit. In the course of three days aphonia had become complete. Preparations had been made for a rapid tracheotomy should suffocation seem imminent. A tracheotomy had finally been demanded for an acute attack of suffocation, and this had given great relief. At midnight, however, the man had died suddenly of heart failure. At the autopsy a thick membrane was found extending from the epiglottis down into the larynx, and in the sulcus on the left side was an abscess cavity. There was also a peribronchitic inflammation which would probably have resulted in time in a septic broncho-pneumonia. There were some ulcers in the cæcum, which were practically healed. On searching the literature he had found that Keen had reported most of the cases, and that most of them had developed well on in the period of convalescence. Often the first symptom had been aphonia, or evidence of suffocation, and death had often occurred almost instantly. In two of the reported cases the patients had recovered without tracheotomy, and two with it. The gangrenous area extended from the epiglottis down two and a half inches into the trachea itself.

DR. E. K. DUNHAM said that he had examined microscopically the specimens from this case. The most interesting of these had been the one taken from the pharyngeal surface of the aryteno-epiglottic fold. In this there had been a diphtheritic inflammation, and a line of demarcation had formed, causing a loosening of the necrotic tissue. A little beneath this line of demarcation there was an acute exudative inflammation with interstitial hemorrhage. Apparently, therefore, there had been two infections; an earlier one causing necrosis of the surface, and a later one causing an interstitial hemorrhage at the base of the granulation tissue. On the inner or laryngeal aspect of the aryteno-epiglottic fold there was a fibrinous exudate on the surface with granulations beneath, and a rather excessive diapedesis of red corpuscles. This exudate was probably due to the second infection. Over the cricoid the condition was very much the same as on the inner surface of the aryteno-epiglottic fold. Nearly all the micro-organisms found were diplococci or streptococci.

Dr. George P. Biggs asked why this case was described as a gangrenous laryngitis.

Dr. Lambert replied that the tissue in the upper and back part of the pharynx had been perfectly black and gangrenous.

A Case of Aneurism of the Aorta.—Dr. Alexander Lambert reported this case. The subject was a man, alcoholic, forty years of age. Syphilis had been suspected but not definitely made out. He had had an attack of pain in the shoulder with dyspnœa some years before. Five years before that attack the man had walked into the Vanderbilt Clinic with typhoid fever, and at that time the aneurism had been discovered. During 1898 and 1899 the man had worked laboriously and drunk excessively. When seen last summer, there had been a large mass projecting out under the chin. This mass measured vertically five and a half inches. Physical examination had revealed evidence of compression of the left lung. The man had left the hospital in August. When seen again, on November 14th, the tumor had extended from the deltoid muscle on the left side across to within three inches of the opposite deltoid. It measured eleven and a half inches transversely and projected three and a half inches. Its circumference was twenty-four inches. At that time the skin had been exceedingly thin over the tumor. About a month later the tumor had measured thirteen inches transversely. Five days after this the man had coughed up a rather large clot of blood. One or two nights afterward the aneurism had ruptured. The autopsy showed that the anterior wall of the aneurism was made up of the skin, and that there was no true sac. The entire thoracic wall had been eroded by the tumor. The blood clot weighed 1,500 gm. The cartilages on the left side had been completely absorbed, and the ends of the ribs had been eaten away. The lungs, trachea, and larger bronchi were normal. There was hypertrophy of the left ventricle of the heart, but the valves were normal. The lateral portion of the arch opened into the aneurism by a large aperture. The interesting feature about the aneurism was that a hole had been made in the aorta by the giving way of an atheromatous patch. The blood had then been diffused into the areolar tissue of the mediastinum, and had become organized there. This mixture of connective tissue and coagulated blood had formed the aneurismal sac.

Dr. Biggs took issue with Dr. Lambert as to the explanation of the formation of the aneurism. He thought there had probably been the usual gradual development due to local weakening of the vessel rather than to a rupture of the vessel.

Dr. Lambert replied that it was probable that the aneurism had started originally like other aneurisms, but there was, at the time of the examination, no longer any evidence of the first formation.

Two Cases of Acute Intestinal Obstruction from Intussusception.—Dr. H. J. Boldt presented specimens from two cases of acute intestinal obstruction due to intussusception. In the first case the intussusception had been caused by a polypus. The second specimen was from an intussusception occurring in a child as a result of a diverticulum in the bowel. He said that he had never met with a case of this kind in which cathartics had not been administered, and he wished to direct attention to the great importance of avoiding the administration of such drugs. If an acute intestinal obstruction could not be relieved in a few hours by the use of high enemata with inversion of the patient, and massage of the intestines, an abdominal section should be performed ere serious symptoms became manifest.

Gangrenous Dermoid from Twisting of the Pedicle.—Dr. Boldt also exhibited a gangrenous dermoid tumor of the left ovary. The condition had been produced by a complete twist of the pedicle from left to right. Apparently the condition had lasted for three or four days.

A Case of Suppurative Metritis.—Dr. George P. Biggs presented specimens taken from a woman, thirty years of age, who gave birth to a full-term child sixty-three days before death. On the seventh day after confinement she had a chill, followed by fever and pelvic pain. Curettage was done two days later and the symptoms gradually abated so that three weeks later she was able to sit up. After two days she was obliged to return to bed for three weeks, but was up again for two weeks before coming to the hospital. She entered the New York Hospital sixty-one days after parturition, and at that time was very anæmic and markedly septic. On examination considerable bloody fluid escaped from the uterus, and a sound passed directly into the peritoneal cavity. Her condition was so bad that a radical operation could not be attempted, but free drainage was established through the uterus and posterior cul-de-sac. At the autopsy marked pelvic peritonitis with extensive adhesions was found. The uterus was but little larger than normal and showed an area of advanced softening 2 cm. in diameter in the anterior portion of the fundus. It was through this area that the sound had passed into the peritoneal cavity. The right cornu of the uterus was 3 cm. in diameter and contained a series of communicating abscesses. In the left broad ligament there was an abscess 3 cm. in diameter. Smears and cultures from these abscesses showed an abundance of streptococci. The Fallopian tubes and ovaries on each side appeared normal except for surface inflammation. Interesting points in the case were the distinct suppurative metritis which the speaker had not seen before, and the long duration for such a process of necrotic softening. The cæcum from this case was much contracted, and its wall was thickened and ulcerated. The process was evidently one of long standing. Partly from a few old tuberculous lesions in the lungs, and partly from the presence of a few miliary tubercles in the peritoneum over the site of a similar ulcer in the ileum, he inferred that this was a tuberculous process.

Dr. Boldt commented upon the small size of the uterus, in view of the amount of sepsis present. Furthermore the uterus was much firmer in consistence than in a case of puerperal sepsis. The suppurative metritis present in this case was exceedingly interesting. He had seen only one other case somewhat resembling this.

Typhoid Infection of the Uterus; Report of Two Cases.—Dr. A. J. Lartigau read this paper. He stated that there were only a few recorded cases of typhoid infection of the uterus. The first case reported was that of a married woman, thirty-one years of age, who had entered the Albany Hospital in 1899. In

November, 1898, she had been sick for three weeks with what had been supposed to be typhoid fever. Her present illness had begun with severe pain in the lumbar and left iliac regions. A diagnosis had been made of ectopic pregnancy, and this had been removed by abdominal section. She had died three days after the operation. The autopsy revealed typhoid fever without intestinal lesions, and acute splenic tumor and an acute hemorrhagic endometritis. The uterus measured 5.5 by 4 by 3 cm., and was of normal consistence. The cavity was patent, and the endometrium soft, red, and congested, especially in the fundus. The mucosa was covered with a quantity of viscid mucus. The microscope showed considerable multinuclear infiltration of the mucous and submucous tissues. The uterus contained the typhoid bacillus and the streptococcus pyogenes. The second case was that of a woman, aged twenty years, who had entered the hospital with a history of having suffered from severe headache and muscular pains for ten days previously. Her history was that of typhoid fever until the end of the second week, when she had become delirious and comatose, and had died quite suddenly, with symptoms of pneumonia. At the autopsy the uterus had been found not to be enlarged; its peritoneal surface was smooth, as was also the endometrium. A number of pin-point-sized hemorrhages were seen in the mucosa. Cultures from the heart's blood, liver, spleen, gall bladder, mesenteric glands, bone marrow, kidney, and urine showed pure growths of the typhoid bacillus. From the uterus the typhoid bacillus had been isolated in pure culture.

Dr. W. P. Northrup asked if the method of differentiating between the typhoid bacillus and the colon bacillus was sufficiently exact as to enable one to make a positive differential diagnosis.

Dr. Lartigau replied that he thought with proper care there should be no longer any question as to the identity of the two organisms, especially when the serum of typhoid patients was used for an additional test.

The Death of the Neuron.—Dr. Ira Van Gieson presented a preliminary communication under this title. He said that perhaps no other cell in the body so readily responded to trifling stimuli as the neuron. The crude pabulum of this cell was built up into the unstable and explosive material which made it possible for the nerve cell to do its work. There was excellent evidence that every part of the long neuraxon derived its nourishment from the nerve cell itself. Whatever material surrounded the slender filament, it was capable of storing a considerable supply of nervous energy. When the catabolic process gained the ascendancy the tip of the neuraxon no longer received its proper nourishment, and the death of the neuraxon proceeded very gradually from the tip toward the centre. When this process was confined to the tip of the axon, its vitality might be alternately restored and destroyed. Even when the axon had been destroyed up to the cell body the latter was still able to generate energy. When this process was going on the nerve cell excreted what he had termed "metaplasm particles." This hypothesis, the speaker thought, thoroughly explained the whole process of fibre death in the nervous system. To summarize: (1) In all chronic fibre death the necrosis proceeded from the distal to the central portion; (2) the rate or intensity of death in the neuraxon was directly proportionate to the preponderance of catabolic over the anabolic process: (3) the presence and excretion of metaplasm particles in the cell body were indications of the death or impending death of the peripheral ends of the nerve fibres.

Dr. P. A. Levene said that the theory of biotonus was first advanced by Max Verworn. According to this theory, the anabolic and catabolic always coexisted in cells or tissues, and the condition of the tissues depended on the relation between the two processes. There were conditions when the process of anabolism was prevailing (growth), or conditions when catabolism was stronger (degeneration), and also when the two processes were in a state of equilibrium. The theory of Max Verworn was corroborated by the speaker in his researches on the developing egg. Although these facts were well known as applied to cells in general, he did not know that an application of it to cells of the nervous system had been made previously. He thought that there was not sufficient proof to consider the "metaplasm granules" anabolic elements of the cell; they could just as well be regarded as catabolic products. The latter view would be in accord with the speaker's studies regarding mucin.

Dr. Van Gieson replied that there were several kinds of metaplasm granules, so far as they could be identified morphologically. He had identified three of these. He had at first been inclined to think that all of the metaplasm granules were anabolic, but he now took the view that they might be both of the ascending and descending kind. The theory just propounded had thus far received most extensive confirmation. Around each metaplasm particle was found a zone of clear material, and this he took to be indicative of the fact that the protoplasm was endeavoring to isolate them. The straw-colored metaplasm granules existed in the living cell, and were not precipitated bodies or artefacts. The pigment bodies he looked upon as metaplasm particles which, for some reason, had been retained within the cell for a long time and had been transformed in their chemical properties.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 5, 1900.

William H. Thomson, M.D., President.

Prevention, Management, and Early Diagnosis of Scarlet Fever.—Dr. Floyd M. Crandall read a paper with this title. His object was to call attention to certain details in prophylaxis of scarlet fever. Children known to have been exposed to scarlet fever, he said, should be kept under close observation, if not isolated. Evidence had been recently presented to show that children who had been in close contact with scarlet-fever cases for several hours after the initial vomiting had escaped the contagion. In scarlet fever there was a distinct advantage over measles because in the latter disease the period of contagion began several days before the appearance of the eruption, whereas the contagion of scarlet fever was present chiefly after the eruption had become fully developed. In ninety per cent. of the cases the period of incubation was between two and six days. The important question of whether or not other children in the family should be sent away must be decided largely upon whether or not these children had been exposed before the appearance of the eruption.

Diagnosis.—Four symptoms occurring together were exceedingly suggestive of scarlet fever, viz.: vomiting, fever, a rapid pulse, and sore throat. The vomiting, as a rule, occurred suddenly with little or no nausea, and was often projectile in character. In his own experience it had been the most constant symptom. Usually the temperature rose quite rapidly. An abnormally rapid pulse was exceedingly suggestive of scarlet fever, to say the least. A pulse of 150 at the outset was not unusual. At the first visit there might be nothing but redness of the fauces, in mild cases, the throat symptoms being very slight at an early stage.

Probably many practitioners in New York City had seen recently a considerable number of cases of grippe associated with eruption, sore throat, and symptoms suggesting scarlatina. A white tongue with red spots was not in the least characteristic of scarlatina, and was seen in many other diseases. The true "strawberry tongue," on the other hand, was exceedingly characteristic, but was a decidedly late symptom. Moreover, it should be remembered that such a tongue did not present red spots upon the whitish ground, but like the strawberry reddened spots on a roughened red ground. The general statement that the disease terminated within forty days should be taken with allowance; the duration was apt to be longer rather than shorter than this period. The fingers should be subjected to special scrutiny before raising quarantine. Desquamation was not the only factor to be taken into consideration in determining the period of quarantine. It had been conclusively demonstrated that there was danger of contagion so long as there was any purulent discharge present, such as a suppurative otitis, a pharyngitis, or suppurating glands. Holt had reported a case in which the opening of a post-scarlatinal empyema in a surgical ward had ben followed by an outbreak of scarlet fever. In some of the mild cases desquamation was very slight, and there was no purulent discharge. In these cases it was well to remember that the desquamation was apt to linger longer than one would expect. Every doubtful case should be isolated until the occurrence or absence of desquamation settled the matter. The disease was often disseminated by the error of diagnosticating as roseola, German measles, or "stomach rash" mild cases of scarlet fever. The question of the advisability of closing the schools during an epidemic of scarlet fever must be settled by a consideration of the particular conditions found in each community. For example, in a rural district where the children would probably be separated if the schools were closed, and where the families knew one another, the close of the schools would probably check the disease. In a large city like New York, on the other hand, the closing of the schools would probably have a directly opposite effect. The speaker urged that physicians attending scarlet-fever cases should provide themselves with a cotton gown reaching from the neck to the feet, and wear it while in the sickroom. The garment should be kept in this or an adjoining room. There was great danger of the physician carrying the disease to others unless such a precaution was taken. Moreover, it was a measure which protected not only the patient but the physician, for the family were usually impressed with the notion that a physician taking so much pains was a careful man, and if a case of scarlet fever should happen to appear in an unexplained way in one of the families attended by the physician, it was not probable that he would be blamed for its occurrence.

Inunctions.—During the stage of eruption a simple bland oil was the most desirable substance with which to anoint the skin. Antiseptics, used in this way, were of little avail, and it was advisable to avoid irritants. Vaseline was commonly employed, but when a more elegant application was desired, lanolin or a mixture of lanolin and cold cream might be substituted. Some cheap forms of yellow vaseline would be found to be decidedly irritating in some cases, and care should be taken not to apply carbolized vaseline over too large an area, for, although it was true that absorption did not take place through the sound and healthy skin, it must be remembered that the skin was not healthy in scarlet fever. When there was much itching, a five-per-cent. boric-acid ointment sometimes gave relief. Resorcin soap was advocated oy some practitioners. Lard was prone to become rancid and hence was best avoided, as irritation resulting from the use of a rancid ointment or oil was apt to prolong the period of desquamation.

Treatment of Scarlatinal Nephritis.—Dr. Robert Coleman Kemp read this paper. He said that the occurrence of anasarca, the general course of the disease, and the favorable prognosis in the majority of cases of scarlatinal nephritis, all afforded reasonable ground for the belief that scarlatinal nephritis was an affection *sui generis*. It developed, as a rule, in the second to the fourth week of the disease. Acute suppression of urine and death might occur before inflammation had had time to take place. Holt stated that albuminuria occurred in almost all cases of scarlatinal nephritis; albumin, casts, and even blood being found in the urine. Post-scarlatinal nephritis was a diffuse nephritis which ordinarily developed in the third week of the disease, and was accompanied by general dropsy. The urine contained a large quantity of albumin and numerous casts of all varieties. Febrile albuminuria, due to acute degeneration of the kidney, often occurred from the second to the fifth day, according to Delafield, and might last four or five days. In febrile albuminuria the urine rarely contained epithelial, hyaline, or blood casts.

Symptoms.—The first symptom often noted in the urine was a fall of specific gravity. Dr. Kemp said that his attention had been first called to this sign by Dr. William H. Thomson. The specific gravity of the urine should be taken twice daily at least, and the daily quantity of urine noted. The next symptom observed was a sudden rise in the specific gravity, associated with a diminution in the quantity of the renal excretion, and with an abnormally high color. At this time there was engorgement of the renal vessels. As a rule, there were no anasarca, no albuminuria, and no pyrexia at this stage. Active treatment should be at once instituted. During this preliminary stage a marked increase of urates occurred, frequently before the appearance of albumin. Anasarca was a typical symptom of the disease, and pain in the back was common. The hemorrhagic form was often fatal in the first twenty-four hours.

Uræmia.—There were usually prodromic symptoms of uræmia, such as vomiting and diarrhœa. With these there might be headache, followed by convulsive twitchings of certain muscles, and later by convulsions. There was often enlargement of the heart. Rapid enlargement of the liver should be looked upon as an extremely unfavorable sign, and one usually pointing to a speedily fatal termination.

Oxygen in Scarlatinal Nephritis.—In the pulmonary complications due to nephritis oxygen should be employed from the very beginning. As oxygen was a good cardiac stimulant, and aided in the elimination of the toxins, there was good ground for using it. It should, for the same reasons, prove of value in cases in which no pulmonary complications existed. The early use of oxygen he believed to be the keynote of success. Whenever there was toxæmia dependent upon the kidneys oxygen was indicated. He only asked that this treatment be given a fair test clinically, instead of being condemned on purely theoretical grounds.

Saline Solution in Scarlatinal Nephritis.—He had employed enteroclysis at 110°–120° F. for periods of from fifteen minutes to one hour, and as often as three or four times a day. As a rule, from three to five times as much urine would be secreted as the quantity of saline solution employed. Hypodermoclysis and saline infusion were also useful.

Carbonated Baths.—These were recommended in uræmic conditions, given at a tempearture of 98°–100° F. Such a bath at a temperature of 100° F. felt almost as hot as an ordinary bath at a temperature of 105° F. These baths were useful also for reduction of temperature, and had the advantage of being more stimulating. In this connection, a very convenient portable rubber bath-tub was exhibited—a device which was likely to be found especially useful in rural districts.

Sources of Contagion.—Dr. H. D. Chapin expressed the opinion that the type of scarlatina had changed in recent years, having become milder. He had experienced considerable difficulty in differentiating between a very mild type of scarlatina and a severe grade of rötheln. On the second or third day of scarlet fever the tip and edges of the tongue were apt to assume a peculiar red, beefy appearance, and the papillæ became prominent. He looked upon this sign as of some diagnostic importance. In many cases it was impossible for the family to have a separate attendant for the child sick with scarlet fever, and here the mother or other attendant should be directed to keep a special gown for wearing in the sick-room only. He believed that the most potent factors in spreading scarlet fever in New York City were the dispensaries. The public schools were almost equally responsible for the dissemination of this and similar diseases, largely because of the unsanitary custom of having the outer clothing of the pupils crowded into ill-ventilated wardrobes. Regarding the occurrence of albuminuria, the speaker said that diarrhœa and very many other ailments of early childhood were apt to be associated with albuminuria. For this reason it did not seem to him practicable for the average physician in the average family to carry out the elaborate study of the urine advocated by Dr. Kemp. His experience had been that the first clinical sign was usually a puffiness about the eyes.

Period of Incubation.—Dr. C. G. Kerley said that at one time he had had an opportunity of observing and studying carefully, in an institution, an epidemic of one hundred and nine cases of scarlet fever. The majority of these had developed the usual manifestations of scarlet fever within five days, but in one the period had been seven, in another twelve, and in another fourteen days. He heartily agreed with the reader of the first paper, that the "strawberry tongue" was of no diagnostic value whatever. The rash was also very uncertain; he had seen it disappear in a very few hours. The lower part of the abdomen and the lower part of the thighs were the favorite locations for the eruption. Sometimes the temperature was very moderate. If scarlet fever was present, there would always be a marked congestion of the throat. In his experience the period of quarantine had been from four to six weeks. The desquamation was prone to continue on the hands and fingers in spite of the most assiduous inunction. He wished to insist upon the fact that the mildest cases of scarlet fever were capable of communicating to others the severest types of the disease. The sick-room should be large and the temperature not allowed to go over 70° F. The inunctions not only prevented the spread of the disease, but allayed the irritation and reduced the fever. His most successful treatment for cases of scarlatinal nephritis and acute suppression of urine had been the use of colonic washings at a temperature of 110° F.

Varying Type of the Disease.—Dr. J. E. Winters said that at times scarlet fever was so severe that almost every case terminated fatally, whereas at other times the disease was exceedingly mild. While the truth of this was generally admitted, there might come under observation a series of mild cases, and, at the same time, a few very severe ones.

Isolation Most Effective.—Regarding the control of the infection the speaker said that there was no other disease so easily controlled by isolation as scarlet fever, although the contagium of the disease was exceedingly tenacious of life.

Nature and Treatment of Scarlatinal Nephritis.—He thought very few physicians had seen scarlatinal nephritis terminate fatally. There was good authority for the statement that scarlatinal nephritis did not occur in the early stages of the disease, and he would assert positively that albuminuria was no more frequent in the early stages of this disease than in measles; but that, if albuminuria did occur in the early stages, it never developed into the scarlatinal or post-scarlatinal nephritis without an interval in which there was no evidence of renal disease. He did not believe that the scarlatinal poison was the cause of scarlatinal nephritis—indeed, such teaching seemed to him most dangerous because it was likely to lead to carelessness. It was a fact that it occurred chiefly in epidemics of a mild type, and in the mild season of the year, and, for the most part, in dispensary or tenement-house practice. His own opinion was that scarlatinal nephritis was the result of a neglect to attend properly to the condition of the skin. A statement that had been made many years ago, and that was as true now as then, was that scarlatinal nephritis occurred almost invariably on the twenty-second day. Again, it occurred most commonly in those children who were allowed out of bed and around the room too soon. Scarlatinal nephritis was in every instance a glomerular nephritis, and was always announced by a rise of temperature, from twelve to twenty-four hours before any other symptom or even before the urine gave warning. The Malpighian tuft might become so engorged that the two capsules about it would fill up the space naturally existing between them, and the result would be acute suppression of urine. The plain indication for treatment was to diminish the quantity of blood in the Malpighian tuft, and for this purpose he would certainly not resort to the use of saline solution; but, on the contrary, would administer aconite up to its physiological effect. Such medication would be quickly followed by a return of the urinary secretion. While this was being done another indication was met. Free perspiration was at the same time induced, and hence the kidneys were relieved and elimination greatly aided. This should be encouraged by the use of hot wraps, and the bowels should also be effectually emptied. He believed there were other types of nephritis in which the only treatment which would prove effectual was that recommended this evening for scarlatinal nephritis, but he would most emphatically dissent from adopting such a plan of treatment in the latter disease.

New Instruments.

A NEW GYNÆCOLOGICAL PAD.

By W. J. GREANELLÉ, M.D.,

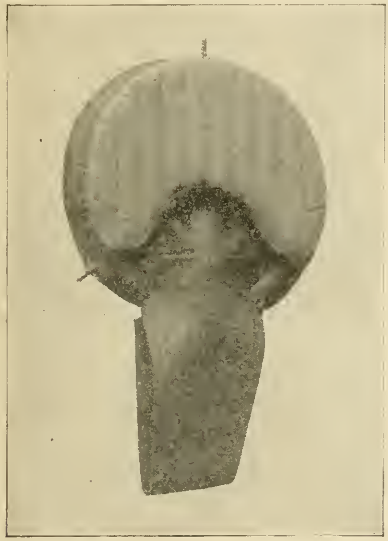
NEW YORK.

Serviceable as it is, the Kelly pad has been more or less disappointing in this: that, even with the utmost care, one is apt to find some back drainage has occurred, and that there is more or less wetting and soiling of linen under the small of the patient's back. This is particularly the case in house practice, where the weight of the patient on the usual woven-wire spring-bed cannot always be prevented from causing sagging by the expedient of putting a board (I usually ask for a "cutting board") under the mattress.

I have worried and labored over this, using all manner of contrivances to prevent it, and have in but few cases succeeded, on removing things, in finding a dry bed, until I adopted the plan of folding a blanket in a suitable manner to permit its use as a support to the top of the pad, favoring drainage toward the sleeve only.

Finally I hit upon the elaboration of this idea, which has been well worked out for me by the Davidson Rubber Company. From my drawings and description they have made the pad shown in the accompanying cut. It consists in the simple addition, on the under side of the Kelly pad, of a crescentic air-cushion, so applied as to provide a firm support to the top of the pad when inflated and in use. In this way the floor of the pad under a patient's back and buttocks is maintained on a level higher than that of the entrance to the sleeve, even in a fairly soft bed. The cushion can be inflated partly or completely, as any one case may require. In addition, the floor of the pad lying in the helix of the crescent, and leading into the sleeve, is made a little broader than the actual measurement across the space, in such wise that it sags somewhat, causing a depression to appear, leading all drainage directly into the sleeve.

I find this arrangement very serviceable and practical, preventing, as it does, the wetting of clothing and linen. When not inflated, the new pad may be folded so as to take up but little more space than the Kelly pad, fitting readily into one's obstetric-bag or ordinary satchel.



I am indebted to Prof. G. C. Mason, of New York University, for the plate.

University Heights.

A NEW MODIFIED URETHROTOME.

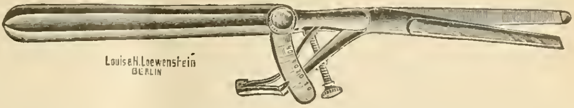
By FREDERIC BIERHOFF, M.D.,

BERLIN, GERMANY.

In the performance of the simple operation of meatotomy, the use of the ordinary meatotomes often results unsatisfactorily to the operator, this result being due usually to the lack of any gauge as to the desired size of the cut. Especially is this the case with the beginner. In order to remove this difficulty I have had the accompanying meatotome constructed. It is a modification of the Collin-Oberländer meatotome, and is furnished with a scale and indicator, by means of which the exact sized cut desired may be obtained.

By setting the larger screw, the indicator may be set at any desired point upon the scale, which is marked in divisions of tens and subdivisions of fives, from 10 to 40 of the Charrière scale. This screw also checks the extent of the excursion of the short arm, and, in consequence, of the cutting blade.

In using the instrument, the larger screw is set so that, when the blades are opened to the fullest extent, the indicator marks the desired size upon the scale. It is then inserted, closed, into the urethra, and the blades being again fully separated, is withdrawn open, an even cut, through all the tissues traversed, resulting.



The little instrument, which was made for me by Louis and H. Loewenstein, of Berlin, has given very satisfactory results in actual use. Repetitions of the operation, in order to attain the requisite size, are avoided, as are also the unsightly effects of too extensive an incision.

Medical Items.

Boys Gasoline Drunkards.—According to the Philadelphia *Ledger*, the police of a small Pennsylvania city were much mystified by finding boys fast asleep and in a semi-conscious condition, stowed in vacant houses, sheds, and brickyards; it was finally discovered that the boys had gotten into this condition by inhaling the fumes of gasoline, and some of them have really become gasoline drunkards.—*Scientific American*.

Suitable Food.—The adaptation of a great variety of suitable foods to meet the different conditions of the imperative requirements of man is influenced by climate, the food of a cold climate differing from that of a warm one; by occupation, the laborer requiring coarser food than the brain worker; by bodily health, the sick cannot be fed like the well; by idiosyncrasies, through which are precluded the use of certain articles of food which are poisonous to the system and which after eating exhibit their effects in cutaneous eruptions, as urticaria, erythema, and other like symptoms.—Dr. De M. Blocker, Chattahoochee, Fla.

Sensational Sanitation.—The aim of sanitary teaching should be to encourage better environment of the individual, of healthful living, comfort, happiness, and peaceful repose; not of excitement, fear, and superstitious awe. Therefore when those who are charged with the responsible duty of caring for the public health, seemingly for personal notoriety and sensational effect unnecessarily parade to the public slight errors of sanitation or magnify the existence of contagious disease, a crime is committed in the name of sanitation because of the injurious influence upon the timid and nervous, who are thus given the opportunity to exaggerate fears and not only to invent but to circulate all kinds of sensational rumors.—Dr. Joseph Y. Porter, Key West, Fla.

A Wonderful Triumph in Surgery.—According to *Lloyd's Weekly Journal*, London, a remarkable feat in surgery has just been achieved by Dr. Hermann von Schrötter in the clinical department of the University of Vienna. A boy, aged twelve years, had swallowed a piece of lead of the size of half a sovereign, which, passing through the trachea, descended into a bronchus of the second order. Dr. Schrötter extracted this piece of lead without tracheotomy and even without using anæsthetics; the operation was, nevertheless, quite painless. This, it appears, is the first time that a bronchus of the second order has been penetrated and a foreign body extracted from it without a surgical operation. The extraction was effected under the guidance of Dr. Schrötter's eyes. First, by means of the Roentgen rays the piece of lead was located at the height of the fourth rib; then Kilian's (Berlin) bronchoscope was in the ordinary way introduced into the trachea and electrically lighted up, and the piece of lead was at last extracted by a pincette expressly constructed for the purpose. Professor Kilian has suceeded only once in introducing his bronchoscope into a bronchus of the first order, and then only by performing tracheotomy.

Tincture of South African Karoo for Dysentery.—In tropical dysentery an extract and tincture of the South African karoo, collected and introduced by Mr. John Maberley, have proved of great value, not only in dysentery, of which one hundred consecutive cases treated with the drug are reported by Mr. Maberley with only one death, but also in hemorrhagic ulceration of the stomach and intestine. The drug has a long-standing reputation among the natives and Boers, but has only recently been identified and used in Europe in cases of acute and chronic ulceration of the stomach and intestines.—*Lancet.*

Housing the London Poor.—The housing-of-the-working-classes committee of the London County Council intends, says *Lloyd's Weekly Journal*, shortly after the Christmas recess, to ask the sanction of the council to a large scheme for housing the poor in the neighborhood of Tooting. The site of the proposed new buildings is known as the Totterdown-fields site, and consists of about thirty-eight and one-half acres. The purchase price is agreed at the rate of £1.150 ($5,750) an acre, so that the total amount will be about £44,500 ($222,500). The cottages which it is proposed to erect on the site will be constructed so as to provide for two families each. They will each consist of two self-contained tenements, one of two and one of three rooms. Separate gardens will be provided, and on an average not less than thirty cottages will be built to the acre. The rent of the tenements should average about 7*s.* 6*d.* ($1.90) per week. The committee are unable at present to state precisely the cost per cottage, but it is probable that the total cost of land, road and buildings will be about £500,000 ($2,500,000).

What Becomes of the Wounded?—A British weekly journal says: "An army loses far more of its strength through its wounded than through its killed. In the first place, there are four or five wounded to one killed, and in the second place the dead men give no trouble, while the wounded require an immense number of noncombatants to attend to them. A great many of the wounded return again to their duty. But, as a rule, more than half of them take no further part in the war. Probably the same thing is occurring out in Africa now as occurred in previous wars, for the effects of the new weapons do not seem to differ greatly from those of the old. In that case it is easy to calculate what our generals lose by having so many men wounded. If they fight a battle, for instance, in which one hundred are killed and wounded, the probabilities are that twenty would die on the field, twelve of the wounded would die later on, twenty-one would be invalided home, while forty-seven would return cured to duty. These are the averages for big battles in which there are several thousand casualties."

Soldiers on British Transports.—"The treatment of our soldiers," says an influential English journal, "on board the transports calls for a searching inquiry. Letters which we have seen from men who sailed in the *Kildonan Castle* and the *Nubia* reveal disgraceful mismanagement, if nothing worse. The supply of eatables was insufficient, the quality most inferior. When the men complained, they were treated with indifference, though food had to be thrown overboard by reason of its absolute rottenness. Need it be said that after three weeks of such treatment the men on their arrival were utterly unfit to sustain the fatigue of a long railway journey and heavy marches? If these complaints came from one or two troop-ships they might be passed over, but the same scandal attaches itself to all. Those who are the cause of our troops being treated like cattle deserve the severest punishment that can be given them."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 7, 1900:

ON THE FORMATION OF AN ARTIFICIAL ANUS.[1]

By ROBERT F. WEIR, M.D.,

PRESIDENT OF THE MEDICAL ASSOCIATION OF GREATER NEW YORK, AND OF THE AMERICAN SURGICAL ASSOCIATION, ETC.

AN artificial anus is fortunately required in but comparatively few conditions. It is demanded, for example, in the rather rare instances of total or dangerous obstruction of the large bowel; in which cases the opening may be made just above the stricture, if the seat of this is recognized, or at a place of election, if the site of the obstruction remains undiscoverable. It is also resorted to when extensive and often painful intractable ulcerations of the rectum exist, whether they be of syphilitic, tuberculous, or cancerous origin. When so employed, the principle of rest of a damaged part, with withdrawal of the irritation of the fæces, generally benefits the local conditions, and even in malignancy ameliorates many of its distressing symptoms. It is further and rightly employed in certain rare conditions of amœbic or follicular ulcerations which are usually confined to the colon. Here, besides the rest that is afforded to the damaged mucous membrane, the new opening, which is usually in these troubles placed high up, allows medication to be applied in either direction throughout the whole extent of the large intestine. It is also performed for the relief of an imperforate rectum. Of increasing importance, however, is the creation of a false anus as a preliminary step in various surgical operations on the rectum which look finally to its removal, total or in part, for neoplasms, or possibly for extensive and more benign ulcerations. Here, as in nearly all the preceding cases, the part to be played by the artificial anus is intended to be but a temporary one, the deviation of infecting fæces; the enforced rest of the bowel, with the greater ease of treatment through the two openings, one the natural anus, and the other the artificial one, aids and often secures a cure, after which the need of the adjunct anus passes away. Then the additional and now no longer required opening in the bowel has only to be closed, and the function of the cured intestine is fully restored.

This side-tracking of the fæces through an artificial anus in the iliac region (for lumbar colostomy may be regarded as an extinct operation) was first suggested by Pollosson in 1884, and was later rendered popular by Schede in 1887. It is now in frequent use as the first step in severe rectal operations, that is to say, in those that bring about much exposure of the parasacral tissues. Its use diminishes the risk of sepsis, and when suture of the preserved anal end of the rectum to the drawn-down sigmoid end is carried out, after the removal of a cancerous section of the bowel, it promotes favorable union. Hence, for these reasons it is well worthy of consideration.

There is evidence which becomes weightier with gathered experience, that an artificial anus should be employed as a permanent factor in certain troubles to which it has hitherto been applied only as a temporary help. I refer now not only to those well-known cases of inoperable cancer of the rectum in which the relief by a colostomy is all that surgery can do, but to those instances in which either the ulceration or stenosis, though not malign, is so great, so rebellious, and so distressing, that colostomy only is to be thought of. To these should be added not only the more common form of severe rectal trouble, the low-down cancers, where after their extirpation an incontinent artificial anus is usually left, but also those cancerous involvements that demand extensive removal of the gut. In all these conditions it is felt with augmenting conviction that the temporary nature of the artificial anus should be changed to the formation of a permanent opening.

This brings me to the presentation of the differences of intent and technique that exist between a permanent and a temporary artificial anus.

In the temporary false anus, as has been alluded to, the surgeon has to keep in mind that in the near future he must close up the opening he has just effected in the intestine, and hence he finds that the diversion of the fæces from the bowel situated below the artificial anus is not the easy job that he has anticipated, because his future reparative operation demands that the distal leg of the loop of intestine that has been opened should be near to the upper or proximal leg so that they can be readily joined together when the proper time arrives. With the establishment of a permanent artificial anus no such difficulty arises. The surgeon then may deliberately cut the bowel in two primarily, or after waiting a day or two (if time is afforded); or, better still, he may close up, by inverting Lembert sutures, the distal opening and leave it thus in the wound, or even do more than this—he may, after closing the rectal end, drop it back into the abdominal cavity, as Schinzinger, in 1881, and Madelung, in 1884, have advised, and thus obtain the surest way of keeping the fæces from slipping by the artificial opening, and accumulating in or disturbing the bowel below.

The attempts that have been resorted to to render effective, as a fecal outlet, an artificial anus as ordinarily established in the left iliac region, have been many, and few have any positive value. It may be interesting, I think, to run over some of these trials.

The classical and older way of performing a colostomy was by an incision two and one-half to three inches long, the centre of which was on a line running from the anterior superior spine of the ilium to the umbilicus and one and one-half inches inward from the iliac spine. The skin, muscles, and peritoneum were cut through, the finger was introduced and the large bowel hooked up and drawn to the surface, and duly recognized by its band or by its epiploic fringes. If any difficulty was felt in finding the bowel, the surest way was to pass the finger inward along the hollow of the ilium until the bowel or its mesocolon was felt. Formerly on being exposed it was customary to suture it by many stitches to the incised skin, in the centre or at one end of the wound. Some surgeons would, before doing this, carefully draw forward and sew the peritoneum to the skin, in order, as it was said, that a broader surface of plastic union with the peritoneum of the bowel might be offered. This extra care, I may here state, is a wasted effort, for while perhaps a wider adhesion is so effected, yet when the stitches are removed or melt away, the adherent bowel sinks often quite deeply in the wound, because, although adhesion between the serous surfaces goes on quickly, it progresses much more slowly between the exterior of the peritoneum and the muscles which have been brought face to face by this circumferential suturing of the peritoneum. Two improvements which have come into the above technique, and that have risen into general esteem, are appropriately to be mentioned here. First, by the teaching of Maydl in 1888, and Reclus in 1889, surgeons have learned that it is entirely unnecessary to use any sutures whatever to hold the bowel in its protruded position. Maydl simply drew the bowel out through the opening far enough to show the attachment of the mesocolon, and then through this, just below the intestine, was thrust a rubber or glass rod, or sometimes a rather thick and long mesh of iodoform gauze (see Fig. 1), on which the loop of the bowel was slung for seven to ten days, sometimes longer, by which time adhesions strong enough to safely hold in position will have formed. Sutures were seldom used to fasten the bowel to the skin unless an immediate opening for the escape of fæces was urgently required. The second improvement is not so satisfactory a one, though it is in the right direction. Its consideration, however, will lead me into somewhat of a digression which I trust you will excuse. The great advance that has been made in the treatment of appendicitis by the use of McBurney's plan of separating rather than dividing the muscular layers of the abdominal wall is well known to all here present. This was published by its justly distinguished author in 1894, but the endeavor to utilize the musculature of the abdominal and pelvic wall to control the surgically created outlets of the stomach and intestines dates back many years anterior to this. Howse,[1] an English surgeon, was in 1879 the first, I believe, to apply this idea of splitting or pulling apart the muscles to obtain a sphincter-like grasp of the rectus abdominis muscle for gastrostomy. Von Hacker, in 1890, popularized this method by using the same muscle in a similar operation. Gersuny made a figure-of-eight twist of the same muscular fibres about the stomach opening. Without, however, going through all the improvements that have been evolved for this purpose in gastric surgery, I will only ask your attention to two of the later efforts in this direction, since they appertain, as will be shortly seen, to the present mode of formation of an artificial anus. Sabaneef and Frank as well as Hartmann have suggested that, in a gastrostomy, in order to render the opening retentive, the protruded stomach should be drawn, not vertically, as in the preceding method, but through a laterally split left rectus muscle, and sometimes be further made to open on the skin surface by a second incision some little distance from the emergence of the viscus through the peritoneum which had been divided through the first incision. Without more words at this time, I can now go back, after calling your attention to Figs. 2 and 3 to illustrate more clearly the foregoing remarks, to the question of the artificial anus. For since 1892, when I began to employ von Hacker's plan of gastrostomy, I have applied the same idea to my colostomies,

[1] Holmes: "System of Surgery," 1883, vol. i., p. 801.

and in 1894 made a vertical incision through the left edge of the rectus muscle, separating the muscular fibres, and drew the bowel out there and fastened it after Maydl's plan. It worked better than by incising the abdominal wall, but it required for anything like an improved control that the intestinal opening should be subsequently much narrowed by several clippings-away of the mucous membrane. Von Hacker has lately[1] advised the use of the rectus muscle in colostomy by splitting it both vertically and laterally as Hartmann has likewise done, and Roux,[2] of Lausanne, has further suggested that the emergence at the bowel should be made through the rectus muscle at the symphysis, hoping by muscular action and by conjoining this with a decided gouging out of the top of the pubic bone to secure a more perfect fecal outlet. Maydl,[3] to obtain this sphincter action, as early as 1888 (thus antedating McBurney six years), suggested separating the muscular fibres of the abdominal wall rather than cutting through them, and since 1892 my colostomies have been done in this fashion.

With the increased rapidity of operation as secured by Maydl's scheme, and by the use of the sphincter grasp of the separated muscles, an improvement was certainly made in the operation, but it was not yet perfect, although Maydl had further enhanced the value of his method by sewing together for a short distance the two legs of the loop beneath the rod or iodoform-gauze support. He endeavored by this to increase the spur that would be formed in this way by the strongly kinked inferior wall of the bowel. This formation of a spur was an idea of importance. It originated with Verneuil, and has been carried out more systematically by Bodine in 1897 (see Fig. 5). This latter surgeon sewed together in a very thorough manner the afferent and efferent legs of the intestine for a distance of nearly six inches, if such a length could be drawn out at the wound. The bent-up bowel was then replaced within the abdomen, leaving its end projecting, which was duly secured by several sutures. If delay can be had, and in nearly all cases save for acute obstruction such can be obtained, the opening of the bowel should be postponed for at least twelve hours, by which time, and often in less, sufficient adhesion will have taken place to prevent peritoneal infection, particularly if the opening of the bowel then made be conducted with gentleness. This secondary opening can often be postponed until the colicky attacks of pain warn one of the accumulation of gas above the surgical obstruction. Then a small opening is made with a knife or with a thermo-cautery above the supporting rod or mesh, tolerably close to the skin. If the artificial anus is to be of a temporary nature, the opening should be a longitudinal one; if likely to be a permanent one, it is better to be a transverse opening; but in either case it should at first be a small one. I lay some stress on this point, for I have found that patients with small openings, even if the ones first made have subsequently to be enlarged, do better and soil themselves less than when such are large. On the other hand, a large opening with a good spur and with a decided crowding on the distal leg to narrow it[1] (see Fig. 6), often gives the best security against the slipping by of fæces into the lower bowel. Hence my endeavor is to enlarge the opening little by little, making it at first only large enough to allow gas to escape

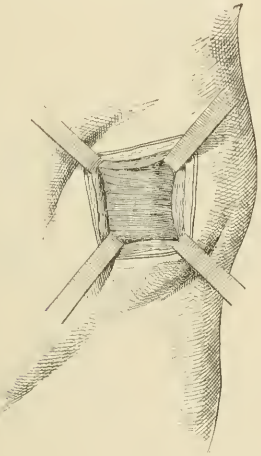

FIG. 4.—Maydl's Intermuscular Separation. First layer only shown.

and to relieve the patient from immediate distress, and subsequently by additional enlargements to secure the end desired. After a time there may come eversion or pouting of the mucous membrane. This may attain an annoying and even a painful size, and often becomes difficult to manage. A little of it is considered a good feature, as it makes a more cleanly discharge of fæces and allows the surrounding skin to be more easily protected. Lauenstein even advises leaving several inches of the bowel to protrude beyond the skin for this purpose, and also for better retentive compression; but no one has followed his example, and he himself has abandoned the plan. This protrusion frequently abates as the inflammatory thickening of the part subsides, but it often persists. This mishap can better be avoided at the time of operation than remedied afterward. Then this expedient can be resorted to: after the loop of intestine is hooked out of the wound by the crooked finger of the surgeon, the upper end of the bowel should be pulled down until it becomes taut, and by keeping the upper leg of the loop as short as possible the subsequent tendency to prolapse is much diminished.

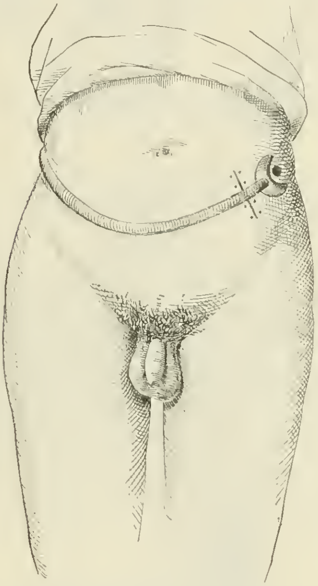

Fig. 7.—Paul's Artificial-Anus Truss.

In spite of all this care, and of even the more radical treatment of cutting away all the bowel projecting beyond the Maydl supporting bar or mesh, and thus creating what has happily been described as the double-barrelled shotgun anus, fæces from the upper opening will from time to time escape directly into the lower bowel, or indirectly from the upper bowel into the retaining dressings, and thence into the lower opening of the intestine. Hence it is not unusual to hear of additional devices being presented to meet this imperfection in the operation. Of the many that I have tried, I will only mention two. One of them is to insert at the time of the operation several large Lembert sutures transverse to the axis of the bowel below the supporting bar, so that the lumen of the intestine is more or less completely shut off by deep wrinklings of its wall. The other is, when the test of time has shown that the anus is not satisfactory, to cut away deliberately, under a cocaine swabbing, the mucous membrane for a space of half an inch all around the lower opening, so as to induce a contraction sufficient to prevent or diminish the flow of fæces toward the rectum, and yet not render too difficult the subsequent closure of the artificial anus when its purpose shall have been fulfilled.

The spur formation, before alluded to, is not always satisfactorily made in the left iliac region. It is more easily accomplished in the transverse colon, of which kind I now show you a living example, where it was applied through the rectus muscle for multiple follicular ulcerations extending from the anus to the middle of the large bowel. This situation for an artificial anus has received lately the strong indorsement of Koenig, as a preliminary step in a Kraske's extirpation of the rectum, because, among other advantages, it is beyond the line of traction and the interference that can possibly be made by the later sacral step in the operation. In this particular case there was a short spur made by suturing the legs of the loop together, and now, though nearly cured of the ulcerations under medicated applications, forced in through the colonic opening, she has had but little annoyance from incontinence, and has never had any escape of fæces into the bowel below. In the cæcal region the use of Maydl's sling has not worked well in my hands, though Maydl says it is applicable even in this portion of the bowel. I have preferred, when such a high opening was required for an acute obstruction in the middle or uncertain part of the large intestine, to open the cæcum or adjacent ileum after a careful continued or multiple interrupted suturing, with a large trocar and cannula, hoping that after the discharge of a quantity of the fluid fæces, usually found above an obstruction, had taken place, enough relaxation of the distended intestine would occur to permit the introduction of a long rubber tube of good size, which in turn was secured by a purse-string suture in the intestine wall. This device, with some impermeable dressing, as collodion or gutta-percha tissue, conducts the fæces away from the wound sufficiently well to insure, with packing of the wound area with iodoform gauze and a large dressing which it perforates, enough cleanliness to permit rapid serous adhesions. In two instances, as preliminary to an operation for resection of the transverse and high descending colon, I have made an artificial anus in the ileum just above the ileo-cæcal valve. Such openings are objectionable, not on the score of nutrition, but principally on account of the skin irritation produced by the fluid fæces of the small intestine. A marked contrast is seen to this when the cæcum, only a few inches farther down, is opened; when but little damage to the skin is afterward produced.

It can easily be inferred, from noting these various expedients, that the difficulties of fecal control, when once an artificial anus has been formed, are, in spite of all that can be done, very great and very distressing; for there is nothing more disgusting and more depressing to the patient and to his caretakers than a leaking false anus. The surgeon justly considers that he has done well if the outlet permits one or two well-formed movements per diem, which, perhaps, may be regulated as to time by an ordinary enema. Such favorable conditions I have more frequently found when the openings have been kept of small size—of such a small size, I may repeat, that from time to time a little enlargement becomes necessary, or, in lieu of this, the daily softening of an enema is demanded. When, however, a diarrhœa comes on, no ordinary dressing or apparatus will prevent the patient from fouling. Numerous mechanical contrivances have been presented to obviate such mishaps and to plug up the opening. I will not detail them, but will call attention to two that have proved of service, in my experience. One advocated by Paul is fairly well shown in Fig. 7, where a horseshoe truss compresses the track of the bowel, first running beneath the skin a short distance before opening on the surface. A truss with a cup of hard rubber I have sometimes found of service in ordinary direct openings, but my best plug consists of a double inflatable bulb, connected by a hollow hard-rubber tube for ease of introduction (Fig. 8), and furnished with a stop-cock for inflation and deflation. The lower bulb is passed into the upper opening of the artificial anus, and inflation is begun. That this may not make too great traction on the lower bulb and pull it out, the upper bulb is covered by a perforated hard-rubber disc that allows the little apparatus to be held *in situ* by adhesive straps or a well-fitting bandage. An extra tube is sometimes added, provided with a stopcock to permit the escape of gas at will. This was originally derived from Scheimpflug's apparatus for a gastric fistula, but is now merely an improvement on Jacobson's intestinal plug. A belt with an inflatable bag is also employed (see Fig. 9) to arrest the flow of fæces. Sometimes a rubber bag with an inflated edge will, when secured tightly to the body, prevent soiling. When these contrivances fail, large dressings are necessary. Gauze should not be applied directly to the protruding gut, since it adheres, and is painful when detached. It is better first to cover the bowel with one or two broad overlapping pieces of gutta-percha tissue prior to putting on the absorbent dressings.

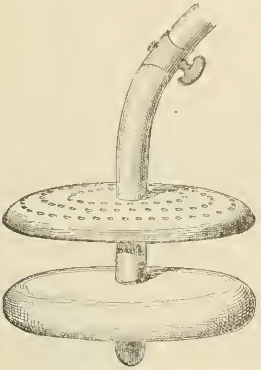

Fig. 8.

Before proceeding to the consideration of the establishment of a permanent opening, a few moments may properly be occupied in speaking of the final closure of such openings when they have fulfilled their mission, as for instance in the case just presented to your inspection the ulceration has healed, or as in other cases the intractable rectal ulcers and stenoses have been overcome, etc. To effect this closure, it is in my judgment better, after having previously well washed out and disinfected both ends of the bowel, to make an incision surrounding the artificial anus, and then to invert the skin and close the intestine thoroughly by suturing. This is merely to protect other parts, now to be opened, from infection. The old skin scar is now to be cut through, or a new incision made alongside, down to the peritoneum, for muscle separation is rarely practicable here a second time on account of inflammatory thickening often present. The abdominal cavity is carefully opened, not too close to the adherent anus, and with the finger as a guide, and cutting a little wide of the intestine, the anal opening is circumscribed and freed. It is then lifted out beyond the skin and the abdominal opening protected by iodoform gauze. The sewn-together opening is left undisturbed, and, after trimming away with scissors any superabundant attached tissue, one or two rows of Lembert sutures are applied, the parts washed off with a sterile salt solution, and dropped back into the abdominal cavity. The gap in the abdominal wound is finally closed by layer sutures.

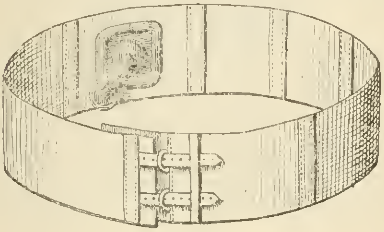

Fig. 9.

Another method has been suggested by Greig Smith and others which is extra-peritoneal. Usually such essays as these fail or are too complicated, but Smith separates the parietal peritoneum for an inch or two, so that not only can the bowel be well lifted up, but the edges of the opening can be inverted and sutured without invading the peritoneal cavity (see Figs. 10 and 11; the dotted lines show the required incision).

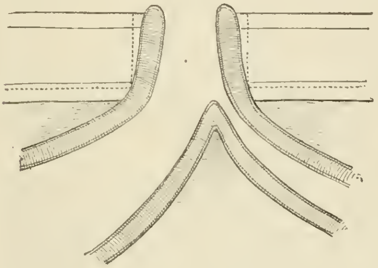

Fig. 10.

Such extra-peritoneal closures have in my own work occasionally succeeded in small intestinal fistulas, but in these days of generally successful asepsis I prefer the intra-peritoneal method. In the seven closures that I have notes of I had no need especially to treat or consider the spur that had previously been formed.

Let me pass on now to the management of the bowel, when, for inoperable lesions in the rectum, or for a total extirpation of the affected bowel, or in those cases in which the rectum has been removed high up by a Kraske operation, a permanent artificial anus has been determined upon. This requires a somewhat different disposition of the bowel. It may be drawn out by the

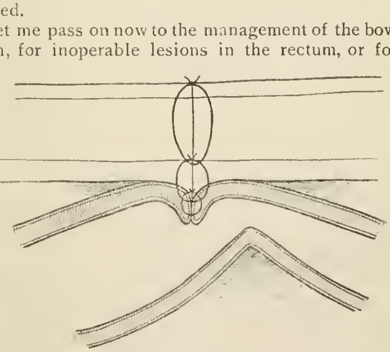

Fig. 11.

usual incision with its muscle separation, etc., and its legs may be sutured together, as Bodine has suggested, and after twenty-four hours the mushroom-like projecting end of the loop can be cut squarely across. This works fairly well with the subsequent contraction of the lower orifice, as has been previously described, and the method and its imitations have a merit that attracts attention. It is that while fæces can or may be kept out, the opening going to the rectum, even if small, will allow the discharge from the possibly tight stricture below to escape upward, or it will aid in washing out or medicating the parts by irrigations from above downward, and *vice versa.* I do not lay very much stress on this, for in the tests I have made on this point I have not found so far any trouble to come from the closure of the upper end of the loop going to the rectum. In those cases in which I practised the double-barrelled artificial anus—in two of them, to be sure of preventing fæces reaching the anus—I inverted and stitched together the peritoneal edges of the lower opening, and effectually shut it up, retaining it, however, in the wound. No unpleasant reaction followed the treatment, and only rarely was an irrigation from the normal anus required.

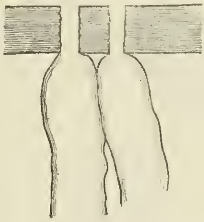

Fig. 12.

But this method of two openings in the groin (and some have placed one opening at one end of the wound and the other at the opposite end [see Fig. 12], and again others have placed the lower bowel above the upper one, or, like Gersuny, have applied here the twist to the upper bowel of one-half to a total turn on its axis, hoping vainly to secure even the moderate success that has been obtained when used in the lower part of the rectum) nevertheless retains the objection of more or less incontinence, and I now call to your notice a plan of operation that, in three instances in which I have lately employed it, has secured a continent anus without the help of any mechanical contrivances, and has effectually disposed of the question of fecal overflow into the rectum below. It is the result of a combination of the suggestion of Schinzinger with that of Witzel. Schinzinger, as has been stated, advised cutting the colon in two at the time of operation and closing the bowel end by inversion and suturing. Then the closed-off rectal end is dropped back into the abdominal cavity, and the other open end of the upper bowel is duly fastened in the abdominal wound. This portion of the bowel could be rendered free from infecting qualities by also being inverted and sutured —as a temporary matter—the sutures being taken out after adhesions had fully formed.

While this procedure is in itself the most effectual in guarding against fecal irritation in the lower bowel, the continence we wish for is not obtained in this way; a further variation is needed, and I have obtained the best success by adding to this closure and dropping in again of the rectal end of the bowel by placing the artificial anus outside the brim of the pelvis as proposed by Witzel. In other words, the upper end of the bowel is transplanted under the skin, to open some two inches below the crest of the ilium (Fig. 13). The intestine is made to come out through the usual opening inside the crest of the ilium; the lower end is cut off, inverted, sewed together, and dropped back into the abdominal cavity (and this was done in the three cases I have operated upon by this method), or it may be retained in the original wound. The upper end, duly contracted by a ligature and disinfected or sutured together, is then drawn through a canal formed for it by separating one layer of the abdominal muscle from the other up to the outer edge of the ilium, where it may be necessary to divide the limiting fascia, so that the intestine can be brought out at a skin incision an inch long, previously made outside the pelvis. This opening was in my cases situated one to two inches below and one inch behind the anterior superior spine. The first, or abdominal, incision is now sutured, and a row of stitches secures the bowel to the iliac skin opening. I preferred to keep the bowel closed for twenty-four hours to prevent soiling of the wound. Witzel, who suggested this idea in 1889, says that his patient then, six years after this operation, always congratulated himself on the excellent function that his artificial anus possessed. Lenkinheld and Borchardt, who also tried it, said that not only was a bandage or compress unnecessary, but that the new anus was absolutely continent for gas as well as for fæces. I was compelled to depart from Witzel's directions to draw the whole loop under the skin and over the iliac crest, for it was too bulky to effect this easily, and hence I cut the bowel in two and dropped the rectal end duly prepared back into the abdominal cavity. This gave more room, and a moderate division of the mesocolon permitted the intestine to be easily drawn out to the required distance. An experience in my third case, however, showed that this division of the mesocolon should be cautiously conducted. In that instance the artificial anus was placed gluteally, as Witzel calls it, for a cancer of the rectum, for which I intended at a subsequent period to remove the anus and rectum and not to attempt to establish a sacral anus. Two weeks after the creation of the artificial anus, as described, I operated for the rectal extirpation, but the patient succumbed from sepsis. At the autopsy the upper end of the rectum, which had been inverted and sutured, was found to be gangrenous in several large spots. This was evidently due to its

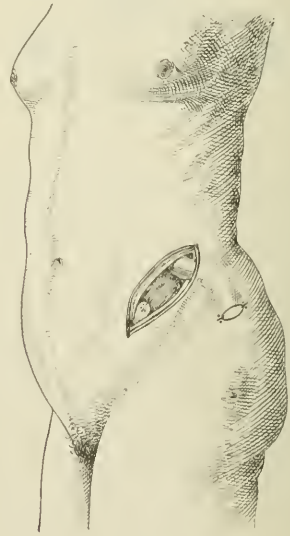

Fig. 13.

vascular supply being interfered with by a too long transverse cut in the mesocolon.

A glance at this diagram (Fig. 14), taken from an article by Kümmel,[1] detailing some successful implantations of the descending and transverse colon in the anal region, will show the anatomical reasons for carrying, in this or any operation to free or lengthen the colon, the liberating incisions in the mesentery at about one and one-half inches parallel to and from the bowel, as this damages least the arterial supply.

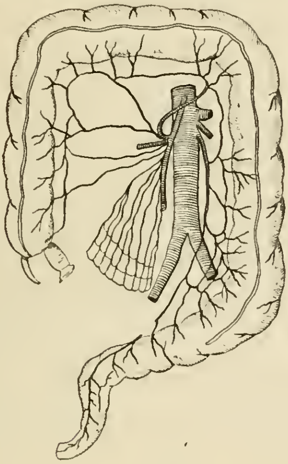

FIG. 14.

In my other cases, both operated upon for intractable and extensive chronic ulceration and stenosis of the rectum, no mishap whatever occurred, and in each there has been complete continence. No bandage or mechanism is used. Only a piece of gauze is applied over the opening, and the weight of the clothing, in addition to the natural advantage of the operative method, seems to afford pressure sufficient to close the intestine effectually as it passes over the bony brim of the pelvis.

One of these patients I have the opportunity of showing you. In her case the escape of gas occurs but seldom, and the finger passed in through the opening appreciates very distinctly the compression of the bowel as it comes over the edge of the ilium. In the other case, living at a distance from the city, the report is a similar one.

In conclusion I may state that the foregoing imperfect review shows: (1) That an artificial anus of a temporary character can be best established by Maydl's operation or by Bodine's modification.

(2) That overslipping of fæces may be prevented by proper spur formation, by narrowing the rectal opening, or by occluding the rectal end of the bowel, which may be fastened in the wound or dropped into the abdominal cavity.

(3) That continence of the abnormal outlet is aided by muscle separation (Maydl) or by muscle bridging (von Hacker and Hartmann), or by the use of inflatable or moulded plugs or other apparatus.

(4) It is only, however, to be satisfactorily effected (though larger experience in this is desirable) by an extra-abdominal iliac outlet (Witzel's iliac colostomy) to be made by opening the bowel outside and behind the iliac spine. In this procedure the bowel is compressed between the edge of the bony pelvis and the skin.

Many other methods have been proposed. Some, like Witzel, have made the outlet externally, but by gouging a hole through the iliac bone. Other schemes have been tried and have failed. A few are so unsurgical that they have fallen still-born. Perhaps some have yet promise, and may in time, their value not now being recognized, develop into methods of note.

I find from my notes that in all I have resorted to the formation of an artificial anus thirty times, with nine deaths, of which there were two from cancer, three ulcerations, and four obstructions. Of these sixteen were for malignant disease, either inoperable or preliminary to operation, nine were for chronic ulceration, and five were for intestinal obstruction.

Among the eighteen cases in which a colostomy was a preliminary to operation or was a curative agent, were seven instances in which the opening was subsequently closed, five by the intra-peritoneal method and two by the extra-peritoneal suture.

INDICATIONS FOR CONSTITUTIONAL TREATMENT OF CATARRHAL AFFECTIONS OF THE UPPER AIR PASSAGES.

By WALTER A. WELLS, M.D.,
WASHINGTON, D. C.,
DEMONSTRATOR OF LARYNGOLOGY, UNIVERSITY OF GEORGETOWN; IN CHARGE OF NOSE AND THROAT DEPARTMENT, GARFIELD HOSPITAL; ASSISTANT ATTENDING PHYSICIAN TO EPISCOPAL EYE, EAR, AND THROAT HOSPITAL.

THE literature teems with reports of cases which illustrate the effects upon other organs and consequence to the general health of nasal, pharyngeal, and laryngeal diseases. Anæmia, malnutrition, deformities of the chest, neurasthenia, migraine, epilepsy, asthma, goitre, functional heart affections, catarrh of the stomach, bronchitis, laryngismus stridulus, urticaria, and melancholia are among the affections which have been attributed to this cause; sometimes reflex, sometimes produced by mechanical causes, sometimes by direct extension of the diseased process, sometimes by transmission through the veins and lymphatics, and sometimes by other, it may be complex and obscure means. How to determine whether or not a supposed effect is in reality due to the nose or throat trouble, as well as how to differentiate the various effects, as to whether of reflex nature or not, has been sufficiently dwelt upon in treatises upon the subject.

Let us now turn our attention to the other side of the picture, viz., wherein the catarrhal trouble figures not as cause but as an effect of the other pathological conditions coexisting, and let us consider in what manner we shall know that the relationship exists.

We will suppose then that we have a case before us of catarrhal inflammation of the upper passages, associated with a more or less grave disease either of some particular organ or of the whole system. How shall we know that the former is not the cause or primary disease, or not a local or idiopathic state (the other trouble being merely coincident), but is in truth symptomatic of the coexisting disease? The latter conclusion, that is, that catarrh is secondary to the other, is justified when it conforms for the most part to the following criteria: (1) No adequate local cause is apparent. (2) Direct local treatment has ultimately failed. (3) The catarrhal inflammation has manifested itself subsequent to the coexistent trouble. (4) Its pathology presents features peculiar to one of the symptomatic catarrhs. (5) Catarrhal inflammations are present in other parts of the body. (6) The supposed cause is sufficient to produce these local effects. (7) Treatment of the associated condition improves in like manner the catarrhal trouble.

It is unnecessary to apply these criteria to such conditions as lues, tuberculosis, lupus, rhinoscleroma, or any of those chronic constitutional maladies which may attack the nose and throat or any other part of the body, and whose diagnosis is given chiefly in the specific nature of the lesion itself. Nor will we need to hesitate long over a number of acute infectious disorders, such as scarlatina and diphtheria, in which in addition to the specific characteristics the sudden and contemporaneous occurrence of both local and general affections is entirely sufficient for diagnostic purposes. Greater difficulty of diagnosis, however, is presented by the concomitant affection of the cutaneous system and of the mucous membrane of nose and throat, between which, as I endeavored to point out a couple of years ago,[1] a very interesting sympathy may be found in their pathological manifestations. Reasons were here given for holding that cutaneous eruptions, more often than ordinarily assumed, could appear as true reflex neuroses of nasal origin, especially erythema of the nose and face, erysipelatous eruptions, urticaria and, perhaps, herpes and pemphigus, and affections of the angioneurotic type. How often inversely the cutaneous eruptions are the primary affections, can be estimated only by careful investigation and application of all diagnostic criteria at our command to each individual case. When such relationship has been for a certainty established, we shall have naturally to put our faith in those remedies indicated in the particular skin affection present.

---

[1] Arch. f. klin. Chir., vol. lix., p. 555, 1899.

Without doubt, the responsibility for much the greater number of secondary catarrhal affections of the upper respiratory organs belongs to the gastro-intestinal system. That diseases of this system exert a direct and decided influence upon the nose and throat is a matter of daily observation. Singers generally recognize that fact, and take advantage of it in avoiding the overloading of the stomach just previous to an engagement to sing. It is well illustrated, too, in the experience of a number of persons in whom every attack of indigestion induces a cold in the head or congestion of the pharynx.

As with the acute, so with the chronic catarrhal affections, which, if not essentially dependent upon disorders of the stomach, at least will suffer exacerbation from such causes. In every case of post-nasal catarrh the condition of the stomach should receive scrupulous attention. It will be found very often that when the application of astringents is futile good results will be obtained by the use of correctives of the gastric disorder, such as pepsin, bicarbonate of sodium, or tincture of nux vomica. These may be given well in combination, in a glassful of hot water just before meals. Or one may find more effective pepsin and hydrochloric acid, with perhaps nux vomica, given after meals.

A form of throat inflammation frequently associated with dyspeptic disorders is that of the lingual tonsil. Amygdalitis lingualis occurs most frequently in middle-aged women, who complain of burning or sticking in the throat, or not infrequently of the sensation of a foreign body, and constant desire to swallow. It is nearly always accompanied with more or less laryngitis, and the voice, even if not hoarse, is generally easily fatigued. The tongue will be heavily coated and more or less dyspeptic symptoms will be found. While local treatment should not be neglected in such patients, the stomach also will generally need attention.

It may seem hardly necessary to refer to the influence of intestinal obstipation upon catarrhal diseases of the throat, since this will be immediately admitted by all who have had any occasion to make observation in this particular, and readily understood by others upon theoretical grounds. Nevertheless, as with many other things which we know, we fail to bear it always in mind. Whether the fault be with the secretions or with the muscular activity of the intestines, their sluggishness must be overcome by properly chosen laxatives, if we are to have the desired success in treating the affections under consideration. Often quite a high degree of anæmia from this cause may be present and show itself in the mucous membranes, especially in young girls. Sulphur is the remedy *par excellence* in such cases, according to some authors.

Moritz Schmidt lays much stress upon intestinal flatulence as a factor in the production of catarrhal diseases of the upper air passages. The abdominal distention, according to him, obstructs the circulation and produces nervous hyperæmia of the mucous membrane. His treatment consists in the complete separation of solid and liquid diet, taking as little as possible of the latter, and only between meals. I believe that regulation of the diet, joined to massage and more or less systematic exercise, are far more efficacious in these cases than drugs or artificial digestives. The most essential thing is sufficient mastication, which may be lacking, either from the individual's carelessness in eating too hastily (the bane of American civilization), or because of faulty or deficient masticating apparatus. If the former is the case, we should explain the danger and emphatically enjoin better habits; if the latter, the cure must rest in the hands of the dentists.

When medicine must be given, I can think of no better prescription for intestinal dyspepsia with flatulence than the following:

℞ Pepsini pur.,
Pancreatin. ext..........................āā 2 gm.
Pulv. carb. lig.,
Bism. subgal.............................āā 4 gm.
M. ft. chart. xii. S. One before meals.

Valvular heart lesions will, in case of failure of compensation, constitute a serious cause of catarrhal inflammation; for the mucous membrane must share in the general nervous engorgement, as indicated by a more or less purplish coloration and increased secretion. It is therefore advisable, in every case which does not readily yield to local treatment, to institute an examination of the heart; more especially if symptoms (such as dyspnœa, palpitation, œdema) should be elicited pointing to cardiac trouble. The treatment will of course resolve itself into that proper for the particular form of heart disease present; and according as the special conditions indicate or the physician's preferences dictate, rest, avoidance of stimulants, and heart tonics will be prescribed, or perhaps the Oertel or Schott treatment or the Nauheim baths.

Among the more unexpected pathological conditions which are sometimes factors in causing and maintaining throat inflammations may be mentioned the floating kidney, which is now known to be present in a very considerable proportion of adult female patients.

Schmalz, Bresgen, and Peyer, and in this country McKenzie, have written upon the relationship observed between nose and throat affections and diseases of the reproductive system. Peyer states that maladies of the genital organs may give rise to intermittent swelling of the nasal mucous membrane (coryza nervosa), abnormal dryness of nose and throat, sensation of heat, arrested secretion, epistaxis, perversions of olfactory sense, hyperæsthesia, anæsthesia, and paræsthesia. It is not improbable that the relationship between these two systems, which, though distant, present certain anatomical and physiological analogies, may be reciprocal, that which is primarily affected in the point of time being primary in the matter of cause and effect. At any rate, abnormalities discovered in this part of the body should be corrected if possible, as thereby only good will be done, even though such far-reaching influences as alleged do not obtain.

Among the diseases whose effects are sometimes seen in the upper air passages, we have yet to mention diabetes, leukæmia, and Hodgkin's disease. In every case of persistent incurable pharyngitis sicca, we must take into consideration the possibility of its being due to diabetes. Hodgkin's disease may give rise to œdema in the mucous membrane, seen sometimes chiefly in the palate and uvula, at other times in the epiglottis or ventricular bands. Leukæmia can be attended likewise with considerable infiltration in the mucous membrane. It may reach such a degree in the glottis as to produce a grave result.

---

[1] New York Medical Journal, October 15, 1898.

Having considered the various specific affections of organs and parts of the body or of certain systems, in their bearing upon catarrhal diseases of the upper air passages, we may now pass to what are known in general as diathetic conditions or dyscrasiæ. These, as a rule, are manifested to a pronounced extent upon the mucous membranes, and in some cases, as scrofula for example, the nose and throat are the places of predilection. It is as impossible to ignore them in treating of nose and throat affections as it is to ignore the mucous membranes of the nose and throat in considering them. Unfortunately for both medical writer and practitioner, the various diatheses or temperaments of the body have never yet been accurately defined and satisfactorily determined; but these boundaries remain hazy and their nomenclature is consequently much confused. This we understand at once to be due to the circumstance that they have no demonstrable pathology, but rest upon the insecure foundation of a symptomatic nosology. Thus it comes that imagination and speculation have made the most of the meagre material at their command, and disputes have arisen which cannot be settled. In the mean time, as discoveries are made in the field of pathological anatomy and bacteriology, we will immediately attempt to adjust them to our purpose, but still in some cases we must subordinate our meagre knowledge to the dictates of convenience.

Scrofula, for example, is now well known to be identical with tuberculosis, but since it lacks some demonstrable gross lesions, and possesses a distinct clinical picture, we find it convenient to retain the term.

Hysteria is a very much abused word, owing not half so much to the backwardness of science as to the ignorance and carelessness of the practitioners, who are wont to call everything hysteria which they do not understand. Clinicians have by careful observation in a great measure made up for the deficiency of the pathologists by giving such unerring symptomatic guides for this disease that it may now be said that he who diagnoses hysteria without discovering the so-called stigmata commits a blunder that should disqualify him for practice from that time forth.

But the greatest whirl of confusion is that which has been thrown about a condition generally passing current under the name of the uric-acid diathesis. We here fall into an apparently inextricable difficulty before which so far both clinical and pathological endeavors have stood helpless, but, as I believe, not hopeless. As the subject is one so inseparable from a study of the nose and throat affections, and so important, too, in a therapeutic sense, the laryngologist is compelled to take it into account. It seems almost impossible to gather from the interminable maze of literature on this subject a perfectly clear and definite conception of the conditions to which this name is intended to apply, owing chiefly, no doubt, to the perplexity which pervades the subject of the origin and formation of uric acid in the living organism. The first difficulty to be overcome is the continual confounding of neurasthenia with the conditions in question, when they are in reality the antitheses one of the other. The second difficulty consists in the error of giving to uric acid both in name and in fact a too prominent place in the pathology of the conditions with which it is found associated. There is beyond doubt a strong undercurrent of opposition to the doctrine which makes uric acid the centre and source of all the trouble with which it is accompanied, and it should be given its right place as a result and not a cause. Instead of being the chief and essential feature it is a by-product or side issue, and we may say a sign of the operation of other and more important phenomena.

Some writers, while minimizing the importance of uric acid, have sought to show that xanthin, paraxanthin, or so-called alloxuric bodies were of chief importance, and that the diathesis should be denominated accordingly. For some time I have been of the opinion that this uric-acid or lithæmic diathesis was not attribuable to the chemical products of whatever nature that were found, but rather to a certain morbid state of the vasomotor nervous system, consisting essentially in an hypersensitiveness and hyperactivity leading to nutritional changes.[1] The signs of the time seem rather to point to change of opinion in favor of this view. Granville[2] has recently written these significant words: "Cullen was nearer to the discovery of the secret than we now are, when he insisted that to the primary moving forces of the organism, viz., to the nervous system, the physicians must look for the cause or causes of gout."

Evidently, a new name needs to be invented which would better designate a morbid state of the nervous system, which underlies these uric-acid phenomena. This state, consisting, as I believe, in an abnormal excitability and over-activity of the nerve cells—that is to say, the reverse of neurasthenia (nerve-cell exhaustion), might, in lieu of some better term, be designated "neurohyperkinesia." As neurasthenia is marked by lowered arterial tension, in neurohyperkinesia, on the other hand, we have increased arterial tension prevailing. The cardinal symptoms of neurasthenia are headache, tachycardia, and insomnia. There is usually a hypochondriacal tendency, with irritability or depression of spirits. Muscular tremor, disordered sensibility, dyspepsia are nearly always present, and to these may be added a long list of other symptoms according to the degree or particular phase which the malady assumes. Neurohyperkinesia, as I understand it, presents an utterly different picture. All who call to mind their patients who have had the so-called uric-acid trouble will bear me out that these, instead of being of the weak, anæmic, wiry type of the neurasthenic, are generally stout or even corpulent, often with flushed face or generally plethoric habits. As a rule, too, they are persons of superior intellectual calibre and vigor. Eczema, hemorrhoids, hay fever, asthma, epilepsy, angina pectoris, true migraine, and a host of affections which are included under the term reflex neuroses, are seen in patients possessed of this diathesis.

There are two types of cases to be distinguished, according to the more or less prominence of a certain group of symptoms. These are (1) neuro-arthritic or gouty; (2) vasomotor sympathetic. The last-mentioned is the one which interests us, as being that in which all that class of affections depending, as I believe, chiefly upon vasomotor irritation arise, known generally as reflex neuroses. They are characterized by their periodically current, spasmodic nature, their want of an organic pathological basis, the occurrence of certain nutritional changes indicated by the urological examination, the etiological influence of psychical factors, and, as a rule, by more or less increase of leucocytes, the striking feature of which is the eosinophilia.

[2] Medical Press and Circular, London, February and March, 1899.

As the nose is probably the commonest source of reflex troubles, the rhinologist will have frequently to do with these symptoms, under the head of nasal reflex neuroses.

Having said so much of diatheses in general, let me now take them with particular reference to their effects upon the mucous membranes of the nose, and the best treatment which should be employed against them.

Scrofula.—The lowered vitality of the system in scrofula is particularly manifested in the proneness of mucous membranes to become catarrhally affected. While I know of no peculiarities in the catarrhal inflammation, the clinical picture is generally sufficient for diagnosis. The characteristic facies (broad nose, thick lips, etc.), the lymphatic swellings, the rhinitis with eczema of the lips, are almost classical. Atrophic rhinitis and ozæna are comparatively common. The association of conjunctivitis and marginal blepharitis as complications will be present in a great proportion of the cases.

Local treatment of the nose and throat affections is not out of place here, any more than in the disease of the eye of the same origin. It will prove of little avail, however, if not supplemented by well-directed internal medication. Our sheet-anchors are cod-liver oil and iodine in some form. The former is best given as the pure uncombined Norwegian product, when it can be so taken, but also in emulsion, of which there are to be found a number of elegant products in the shops; or, if we like, it may be given in combination with the hypophosphites. The indication for iodine is best of all met by an old-time but highly valuable preparation, the syrup of the iodide of iron. The certainty and the rapidity of improvement following its administration are among the most pleasing experiences in medical practice. In some cases, however, idiosyncrasies will be found, and then we must find substitutes. Arsenic, iron in some other form, the hypophosphites, or the syrup of hydriodic acid may be found to suit individual cases. The hypophosphites are thought to be especially indicated in cases of retarded osseous development. Of course, fresh air and supporting diet will be understood to be of prime importance. Salt-water baths, when they are within reach, will prove of the highest benefit.

Hysteria.—The real nature of hysteria is as yet so inadequately known that it is difficult to predicate anything with certainty as to its relation to nose and throat affections. If, as appears to be the case, real structural changes may be produced, it might be said to present the anomaly of a functional disease giving rise to organic changes. Whether or not inflammation may be produced, at any rate those who treat diseases of the nose and throat will with suspicious frequency encounter the associated condition of hysteria, and will be called upon to decide whether at all or how much the hysteria has to do with the symptoms present. About a year ago I reported a case of extraordinarily frequent and long-continued sneezing[1] (ten thousand to forty thousand times a day), going on for a month or more, in which there was such a combination of hysteria and local inflammation in the nose as to baffle all attempts to place the blame where it belonged. Overwhelming doses of sedative or antispasmodic drugs, however, having proved futile in controlling the sneezing, and removal of a hypertrophied middle turbinate having been followed by a cessation of the symptoms, all the *a posteriori* evidence was in favor of a local causation. Hysteria, though, no doubt plays something of a rôle in giving rise to nose and throat symptoms. Anæsthesia and paræsthesia of the mucous membranes are very common attendants upon the hysterical diathesis. Also laryngeal spasms and paralyses and the peculiar condition known as globus hystericus will come quite frequently under the notice of the laryngologist.

As already indicated, in the event of the concurrence of nasal or pharyngeal trouble and a hysterical constitution in the same patient, there may be no small difficulty in discovering their true relations one to another. It is possible that they are independent, but it is also possible that when associated they may act as reciprocally causative factors. Both local and general treatment, at any rate, are in order, and so, while we use our douches, spray, powder, or ointments, or, as may be necessary, our cautery, saw, snare, or curette, we will at the same time not overlook the needs for internal medication. Bromides, valerian, and asafetida have for long time been supposed to exercise a special influence over the hysterical state. We may try them, but I believe the newer therapeutics look rather to rational physical and hygienic methods for the best results. Electricity and balneology are the chief among these, but the *sine qua non* in many cases is a complete change of environment, especially the separation from over-sympathetic and too indulgent relatives.

Neurohyperkinesia.—As in both types of this diathesis, the gouty or neuro-arthritic and the vasomotor sympathetic, the upper air passages play a very prominent rôle, it will be necessary to consider them both, and, for reasons which will become at once obvious, separately. Much has been said recently about the uric-acid origin of catarrhal inflammations of the nose and throat, and it has become certainly established that a relationship of some kind exists. Not only do cases of acute tonsillitis and pharyngitis give evidence of a true rheumatic causation, yielding readily to the salicylates and their congeners, but we must reckon as of a rheumatic or gouty origin many chronic cases of rhinitis, rhino-pharyngitis, tonsillitis, and laryngitis. They are found so often in persons of the gouty, or, as the French would say, neuro-arthritic habits, in persons who have gravel or present other evidences of this diathesis, having manifestations, it may be, such as asthma or migraine, belonging to the sympathetic type, that mistake is out of the question. The appearance in the throat of inflammations of a gouty origin are in a measure characteristic. The soft palate, fauces, and posterior walls of the pharynx will present a highly engorged condition, approaching a degree of bogginess. The palate and uvula will frequently become œdematous. The redness of the membranes is intense, but most marked along the pillars of the fauces. There will be severe pain in the throat, pain and maybe difficulty in swallowing, and soreness in the cervical muscles. In the more chronic forms these symptoms will be less acute, and the patient will complain of intermittent burning or sticking in the throat; or frequently the sensation of dryness, tickling, or stiffness felt in swallowing. The larynx becomes likewise involved, and prolonged use of the voice is impossible or is followed invariably by hoarseness and soreness of the throat and a feeling more or less of exhaustion. The crico-arytenoid joints become, like other articulations, the seat of inflammation, as evidenced by swelling discerned by the laryngoscope in this locality. Gouty deposits are found here, and even in the cords themselves.

Throat specialists who are desirous of obtaining the very best results in these cases of inflammation of gouty or neuro-arthritic origin will, at the same time that they make use of the various topical applications which have been found of service (thiol in glycerin two to four per cent. has proved valuable in my experience), recognize the necessity of resorting to constitutional remedies. However discordant the theories of different authors and investigators on the subject of the etiology and pathology of the diathesis I am discussing, all are agreed in the efficacy of certain medicinal agents and special lines of treatment, of which the most prominent to be mentioned are the salicylates, the iodides, and the alkaline treatment. The salicylates (salicylic acid and salicylate of sodium, and its congeners salol, salophen, salipyrin, etc.) are indicated in the acute cases. The iodides, alone or in combination with colchicum, are chiefly relied upon for the more chronic forms. The salts, which owe their only virtue to their alkaline properties, are given with good results in both acute and chronic cases. It is said (Bence Jones, Chevreuil) that an alkaline medium favors oxidation, which probably explains the good results obtained from the alkaline method of treatment in the gouty habits, as here we have to do with a condition of disturbed tissue metabolism, marked chiefly by suboxidation and increase in the products of disassimilation. By some bicarbonate of sodium is given in large doses, by others bicarbonate of potassium, while phosphate of sodium or carbonate of ammonium is preferred by yet others. Mineral waters that are prescribed for this class of patients depend for their virtues upon the alkaline constituents. The waters having greatest reputation are those containing large proportions of bicarbonate of sodium, as Vals, Vichy, Fachengen, etc. The Carlsbad and Marienbad Springs, which are also very popular, are rich in the sulphate of sodium and magnesium. The lithia waters are very widely advertised and generally used for their supposed efficiency in these conditions.

---

[1] National Medical Review, Washington, May, 1899.

In England, where the gouty habit is even commoner than in this country, the chemical constituents of certain of the mineral waters (Friedrichshall, Seltzer, Kissingen, and Vichy), put in the form of compressed, effervescent tablets, are very much prescribed. These tablets, not only of the mineral waters but also of lithia, lithia and potash, piperazin, etc., have been recently introduced, and on account of their convenience and elegance, having the advantages of occupying small space and therefore of being portable in the pocket, and of ready solubility, producing a pleasant effervescent drink, I have used them for about a year with very satisfactory results. In the present-day practice of medicine we have to look as well to the elegance of our prescriptions as to their physiological effects, as our ends may as well be defeated by the one as by the other. In chronic conditions, in which the patient must continue taking medicine for a long period of time, we must be careful to avoid giving doses which are disagreeable and difficult to take, else the patient will become disgusted and cease undergoing treatment altogether. If lithia is to be given for its therapeutical effects, it is much more rational to prescribe it in certain definite doses (as in tablets of lithia citrate, gr. iii. and v.) than in the so-called lithia water. The indications for alkaline medications are very precisely and thoroughly met by the tablet of lithia and potash combined. The best method to pursue to arrive quickest at the required alkalinization of the system is as follows: As early as the patient awakes two tablets should be taken dissolved in a full glass of water; then before each meal and again at night one or more, as necessary, to bring about an alkaline urine, which will be determined by testing with litmus paper.

The Sympathetic Diathesis.—By this I understand, as said, that type of the neurohyperkinetic diathesis marked by the disposition to the origin of reflex disturbance in various parts of the system. The rhinologist is familiar with this diathesis, having so frequently to do with reflex neuroses of nasal origin, hay fever, migraine, asthma, etc. As a rule he is inclined to emphasize too strongly the local causation, overlooking the important fact that the local trouble would not have produced these secondary disturbances without the existence of a certain underlying morbid condition of the system. Treatment directed to the overcoming of this general diseased state then is in order. If our theory of vasomotor causation be the correct one, we should expect those remedies to be most efficacious which are known to exert a direct depressing action upon the sympathetic. Examine the list of remedies in highest repute for hay fever, asthma, epilepsy, migraine, and angina pectoris (the group of affections most frequently occurring as reflex neuroses and having a close analogy among themselves), and it will be seen that it is the class of sedative or motor depressants which are most in vogue. In all opium, bromides, chloral, amyl nitrite, and nitro-glycerin are used with effect. In addition, quebracho and grindelia, classed as motor depressants, are found particularly valuable in asthma. An apparent inconsistency may be thought to exist in the fact that atropine, said to excite the vasomotor system, is recommended in hay fever and asthma by some. While the first effect, however, of belladonna is excitant, in large doses it produces, on the contrary, a depressant, paralyzing effect on the sympathetic ganglia. The disagreement in the experience of various observers may perhaps be explained by this circumstance. While for each kind of neurosis certain of the class of remedies will be found of greater service than others, and while regard must be had for the special indication in individual cases, in general it may be said that the measures and remedies *par excellence* for all affections (nasal neuroses) falling under the head of the sympathetic diathesis are those which act to depress the vasomotor sympathetic nerves.

For hay fever, in addition to the local treatment which is indispensable, I have found that the best prescription for internal administration is a modification of that of J. N. McKenzie. The only change made is that of the substitution of belladonna for nux vomica, the formula being then as follows:

℞ Zinci phosph.	gr. $\frac{1}{16}$
Quin. sulph.	gr. ii.
Ext. belladonnæ	gr. $\frac{1}{8}$

S. One pill before each meal.

Neurasthenia.—It is not surprising that an affection so common as neurasthenia in this age should be met with in the consultation room of the laryngologist. The mad rush after success, the infection of modern civilization, has naturally drawn upon the reserve force of the overworked nervous system, until eventually, in a very large number of cases, nerve exhaustion or neurasthenia is superinduced. That, however, the association of neurasthenia with nose and throat affection is more frequent than would be expected from the frequency of each separately, is not to be denied. Some have thought from this that the neurasthenia was the product of the existing catarrhal affection, and have described cases which appeared to them to justify this view. But I am inclined to suspect that a careful search into the history and development of such cases will not fail generally to reveal that the commencement of the neurasthenic condition antedates the local trouble, and that other causes have existed, acquired or inherited, which go to explain its presence. At least it is not clear how a local lesion of this kind, however grave or long continued, can give rise to the general disordered state of the nervous system comprised under the name neurasthenia. So far as my experience goes, the nose and throat in neurasthenic patients present objective appearances that are very insignificant as compared with the subjective symptoms. Neurasthenia, then, it seems more rational to believe, is the essential and primary disorder; the nasal or pharyngeal or laryngeal troubles, though real, are secondary, and in a great measure symptomatic;

that is to say, the neurasthenia, if not directly producing the local affection, prepares a ground of such sensitiveness and disorder that a minimum organic change shall give rise to a maximum of symptomatic manifestations. Under these circumstances, our first concern must naturally be the treatment of the constitutional state. For neurasthenia, the requirement above all to be insisted upon is rest from intellectual work, and the withdrawal of all sources of undue excitement. A complete surrender of the occupation, and a temporary vacation spent away in some restful surroundings, may have to be enforced in some cases.

Certain medicines are of demonstrable value, chief reliance being placed in arsenic, nux vomica, and phosphorus and its compounds. Of late the glycerophosphates have come very much into prominence among the French, especially for the treatment of neurasthenia. They are the products of the decomposition of lecithin, an agent known to play a very important rôle in the activity of the nervous system. It was found by Sarano, when introduced hypodermically, to improve digestion, augment the number of red blood corpuscles, stimulate nutrition, and increase the weight. Excellent results have been obtained clinically by the use of the glycero-phosphates by Robin, Kahane, Starr, and others. The different forms of neurasthenia will often require different treatment. Hydrotherapy, rightly employed, is in general of much real service. Most patients are benefited rather by the tepid than the cold douches, according to Sorchet. Insomnia and other symptoms will frequently demand particular remedies. Electricity, massage, and very moderate physical exercise will generally prove of advantage. One of the most recent writers, Dornbluth,[1] advises against too strict dieting, permitting tea and coffee, but interdicting alcohol. He advocates the assuming of the recumbent posture as much as possible, and general faradization with weak currents.

1133 Fourteenth Street, N. W.

A CASE OF FRACTURE AND MEDICAL ETHICS.

By E. S. GOODHUE, M.D.,
LOS ANGELES, CAL.
FORMERLY MEDICAL SUPERINTENDENT, MALULANI HOSPITAL, HAWAII.

A thorough knowledge of the theory and practice of medicine is not more essential to the young doctor than the experience which he lacks at the outset of his career. He may have graduated with honor at one of the best colleges in the country, and be thoroughly conversant with the best modern and scientific methods of treating disease, yet be ignorant of the ways and means upon which his particular career shall depend.

He must know how to adapt himself to the local, social, and professional phases of human nature he touches; learn to be tolerant of faults, charitable toward meddlesome mothers, patient with fools; he must relax his schoolish code, and discover that some very reasonable theories fade into unreality the moment they are applied to a living subject. Just as the dancer learns how to dance by dancing, so the doctor becomes proficient in his art by running foul of all the accidents that befall the average practitioner: ignorant patients, dishonest patients, quackish patients, dilatory patients; good consultants, bad consultants, consultants that take advantage; sin, sorrow, bad bills, malpractice suits, backbiting, foolish gossip, malingerers, inclement weather, night calls, Christian Science, placenta prævia, and the large number of patients that don't follow directions. If he needs the tactus eruditus for successful work in a strictly medical line, he cannot get along without another kind of tactus to guard him on occasion, and keep him from spoiling what good reputation he has gained in his work.

He must learn to be firm with his patients. "You are the doctor" is a fact that will sooner or later be thrown up to him by some patient who has been allowed to have his own way.

He must learn to show a confidence that he may not feel; appear hopeful when he is the reverse, and never express damaging surprises. Early in my practice—a few months after I graduated—I came across a case that taught me a lesson. If the experience shall help any one else, I will report it as briefly as I can.

One Sunday morning, I was hastily summoned to go out some ten miles to see a child that had "put its elbow out of joint." As I was busy waiting for such an opportunity, I went at once, taking with me L—— and an emergency case. We rode over a rough road through a cañon that seemed interminable, and came at last to the house where everybody was anxiously waiting for us. The patient was a girl aged ten years. She had been thrown from a horse while riding "bareback." I was well acquainted in the house, as I had been attending the father of the child, who was convalescing from a severe attack of typhoid fever. He lay in bed near the door opening from the room in which the patient sat crying. The mother, a large Amazonian, stood with her arms akimbo, and a daughter patterned after her mother walked up and down the veranda wringing her hands. Two of the girl's beaux were present, and very soon another daughter with her husband and child arrived. On examination, I found a much swollen and somewhat discolored right forearm and elbow, compressed by a dress sleeve that I cut open. Although there were evident appearances of backward dislocation of the radius and ulna, there was not only no rigidity, but undue mobility, the forearm dropping by its own weight. As the arm was swollen, and the child cried loudly at even the gentlest movement, there being intense pain on pressure much increased by any attempt at flexion, I decided to give an anæsthetic, and soon had the child well under the influence of ether. I was not able to accomplish this without a long parley with the mother, and repeated interference from the elder daughter. They had their doubts whether such procedure was justifiable under the circumstances, and so on. I told them that we probably had a severe fracture, and that with the amount of swelling present and the involvement of the joint it would be necessary to give the arm a thorough examination, which they must see could not be done without an anæsthetic. After some hesitation, they consented. I found that the external condyle was fractured, presenting movement and slight crepitus, while the coronoid process was also fractured, allowing the backward play of the bones of the forearm when the elbow was extended. Evidently the force upon the open hand and extended elbow thrown out by the girl to save greater injury had been transmitted through the radius to the ulna and the trochlear surface. The coronoid fracture was a rather unusual one, but not at all strange under the degree and distribution of indirect force present. The condyloid fracture came from a more direct impulse; a result of common enough occurrence. But although I had some doubts at first as to whether the epiphyses were separated (such an accident being not unusual in children), I soon found that the diagnosis was made easy by the play of the joint in my hands; now a dislocation, now a reduction, according as I extended or flexed the arm. At every moan or motion the child made, the mother and sister would fly to my side, and the old man would growl, "Say, can't you be easier with that child?" Finally, I had to ask the mother and daughter to go into the other room.

---

[1] Münchener med. Wochenschrift, January 16, 1900.

I then flexed the elbow at a little less than a right angle, put it up in a fixed bandage, and left the girl rather comfortable. I asked the mother to watch the hand, and if there was more swelling, and the bandage seemed too tight, slightly to loosen it. I said that I should return in the morning, as the arm ought to be seen every day for a few days, anyway. "Oh, I can't pay fer that," said the mother, "I can't afford to pay for another visit, an' I don't think it's necessary. When a jint's once sot, I don't see that it needs the doctor any more."

In the morning I came at my own expense, although the family was well able to pay for the trip. I found that the mother had all but removed the bandage, and, while the swelling was less, the arm lay extended and as much "out of joint" as ever.

With great care I put the arm up in a permanent bandage as before. I was going to put it in a silicate or plaster-of-Paris splint, but the mother urged so against it that I foolishly gave in to her. As I left, I asked the family to report each day, because I felt very anxious to know the outcome of so serious a fracture. The mother went on to tell me that she had "sot many a jint as well as any sargint." She had fixed her daughter's "public bone" (pubic, I suppose she meant), and she had sent for a doctor in this case only because people might talk.

I heard nothing from the case for four or five days; then the daughter came to my office to tell me that her sister was getting along "right smart." She said that, the next morning after I left, Rosa complained so much of the pain in her arm that her mother thought it was best to take the bandage off altogether, which she did, putting in its place a strip of leather. She had done it up "'bout as you did," and Rosa was comfortable. "I am afraid," said I, "your mother has made a mistake, and if there is deformity you must not blame me. I have my doubts whether you will have a good arm."

"No danger," answered the sister, laughing. "You don't know what a good doctor mother is."

I had come to my professional "pons asinorum." Such a blunder I could not make now, but I did actually let that woman control me and my reputation in the case so far as to acquiesce in her demands. I should have required either absolute control of my patient, or my dismissal from any further attendance upon the case; and why I didn't may have been due to several things, the chief of which was want of experience in dealing with this class of patients. I have found that nearly every doctor has, at some time or another, done something, or failed to do something, for which he mentally "kicks himself" ever after.

Six weeks after the accident I met the mother. She said that Rosa was getting along well; that her arm was somewhat stiff, but not more than it "orter be."

In the mean time, I sent in a bill for services rendered the family, not only in this case, but for the long illness of the father. He was an old toper who, by the goodness of Providence or the interference of the devil, had pulled through an unusually severe run of typhoid fever. During the illness, which was retarded by several complications, the family had requested me to call in their former physician, a homœopathic practitioner, who very courteously expressed his opinion that Mr. J—— was getting along as well as could be expected.

But when I entered the house for the first time, I had an intuitive feeling that my directions would not be carried out; that the ignorance and vanity of the mother would have their perfect work. Had I been wise (even as wise as I am now), I should have insisted upon precedence. But when a young doctor is just getting a foothold in this and that family, trying, as it were, his doubtful skill, he is much inclined to insist less and please more.

The bills were rendered again, bringing no answer. At last they were sent with a suggestive footnote: "Please call and settle at once." I don't remember how many months later Dr. G—— called me into his office as I was going by. There he told me that Mrs. J—— had been to see him with her daughter Rosa; that the daughter had an unsightly deformity as the result of a dislocation probably.

"They have been all about," said he, "to see other physicians, and threaten a malpractice suit. I would advise you to call on these physicians, and explain the case as you have to me."

Like a true friend, this doctor had found out the names of the physicians consulted, and gathered all that would be of advantage to me.

"Well," said I, with all the inexperience of the untried, "let them go ahead; it will advertise me. They have not the shadow of a case at all, and I can bring in other doctors—any doctor—to prove that I was not to blame."

"Go slow," said the old doctor, smiling; "doctors are not all just, not all even honest, and the laws are not on the side of the doctor. I've had a malpractice suit on my hands, and I know what it means. No matter who's to blame, take this little girl into court, dwell on her innocence and youth, show her deformed arm, and the blame will be placed on the doctor that attended her. You have a case if any one has, but the world is a sad pickle-jar, my son, and a great many doctors I know are better at furthering their own interests than at telling the truth."

I went to see the doctors Mrs. J—— had consulted. One was an eclectic. He said that he had seen the arm; it was certainly an ancient dislocation. He did not remember advising the woman to sue, but if he had, he should not now, knowing the particulars. He said that the family were unreliable and unstable. The homœopath said he thought that the woman had no cause for suit, and told her so. The other physician seen was an old army surgeon who graduated in the fifties, and he told the woman that the deformity might be the result of a fracture of the condyles. He had seen such cases after the best of care. I now made another free trip to Mrs. J——'s home. She met me at the door with fire in her eye. "I know what you come fer," she said, striking an attitude, "but you needn't expect to git a cent here. We-uns don't pay sech as you. You may have to pay we-uns afore your bill's collected. My dorter's maimed fer life. The doctors says it a bad piece of work, and one of 'em tol' me not to give his name, as he's a friend of yourn, but he says it's enough to land you in jail."

I talked to this woman from my heart, and left nothing unsaid of all the cruel truth, acknowledging, finally, before I closed my address, that I was to blame for one thing only, and that was in allowing such an ignorant, opinionated shrew as she to dictate to me. Before going I examined Rosa's arm and found the deformity that would naturally result from such a vicious union. But the arm was not very unsightly, and could be used to considerable advantage. But the experience, the lesson, elbowed itself into my memory to stay.

Lynchage is the latest French term applied to executions without the red tape of jury trial. The *Gazette des Hôpitaux* thus designates the removal of certain organs from a man at Falls City, Neb., by a mob, who believed him guilty of assault upon a young girl, thus rendering him incapable of again making such an attempt. The *Gazette*, wrongly we trust, suggests that a medical man may have been in the party.

THE USE OF ELECTRICITY IN CHRONIC RHEUMATISM.[1]

By WILLIAM J. MORTON, M.D.,

NEW YORK CITY.

MR. PRESIDENT AND FELLOW-MEMBERS: The subject assigned to me is the use of electricity in the treatment of chronic rheumatism. First, as to our therapeutic agent, electricity: It is often claimed that we do not know what electricity is, implying hence that its medical administration is a blind pursuit. It was Lord Kelvin, I believe, or at least some one equally authoritative, who remarked: "We know more about electricity than we do about shoemaker's wax." Now, shoemaker's wax is a very simple drug, and it follows, of course, that we know more about the nature of electricity than we do about any drug in the pharmacopœia.

Next, I would remark that we are apt to be misled, and adopt invidious distinctions, if in electrotherapeutics we adhere too closely to the terms galvanism, faradism, and franklinism. In reality these expressions have no place in modern electrical science. They are relics of a bygone time. Unfortunately, they still serve us physicians as a peg upon which to hang what we do know about electrotherapeutics, and therefore I cannot abolish them wholly from my part of this discussion to-night. In truth, electricity is electromotive force, pressure, voltage, or difference of potential, whichever term one chooses to use. And electromotive force may be developed (1) from a chemical cell (galvanism); (2) in an induction coil (faradism); or (3) by a static machine (franklinism); but it may also be developed and modified in many other ways not enumerable under the above nomenclature.

Again, we administer electricity, that is to say, electromotive force, to the patient's tissue, and the result is work performed, represented in joule, namely, heat units, upon that tissue. This "work" done is, first, transformation of electric energy into other forms of energy—electrolytic, when tissue is decomposed; cataphoric, when fluids are moved along and diffused; secondly, excitation of physiological function, when the irritability of protoplasm is excited, and when nerve and muscle tissue and gland cells exhibit their characteristic irritability; or finally, though more remotely, but not less important, mechanical, when muscles contract and set up circulatory movements in arteries, veins, capillaries, and lymphatics. There is, therefore, as is readily seen from the above analysis, no question of galvanism, faradism, or franklinism, as individual entities in electro-therapeutics, but simply a question of the modality of electromotive force and of the nature of the work done by each modality. In regard to modalities, each will vary, as has been said, according to its source, and may constitute a continuous, a periodic, an alternating, or an oscillating current, and one of high or low initial electromotive force, and of high or low frequency, etc. It is then to the sort of work done by varieties in the expression of electromotive force in living tissue that we must look for our curative results. This, so far as we have gone, summarized briefly, is: (1) electrolytic and cataphoric (galvanism); (2) excitation of physiological function (galvanism, faradism, franklinism); (3) mechanical, mainly circulatory (galvanism, faradism, franklinism).

But there remains outside of galvanism, faradism, and franklinism a modern modality of electricity to which we must appeal to obtain our best results in the treatment of not only chronic rheumatism, but also many other diathetic conditions, involving many other chronic diseases or conditions of health. This modality is the high potential, high frequency current (described by the writer in 1881 and in 1891—brilliantly explored and exploited and completed in all its scientific relations by Nikola Tesla in 1892, and by Elihu Thomson; about the same time and independently studied in various further phases by d'Arsonval, and placed upon a firm therapeutic basis by him by positive laboratory experimentation upon men and the lower animals, and now admitted to be the one form of electrization which exerts by far the most profound effect of all upon the metabolism of the human being). This current, in none of its forms, produces any appreciable electrolytic effect, but it profoundly affects physiological function. In some of its forms it excites the neuromuscular mechanism and produces sequent circulatory effects; in others it fails to excite the neuromuscular mechanism, while still setting up powerful metabolic exchanges.

The current which I select for the treatment of chronic rheumatism is the high potential, high frequency current in one of its forms, and the work I accomplish in tissue is to affect both the local and the general metabolism or nutritional exchanges. The current I obtain from a powerful influence machine, using condensers to produce the "static induced current," or using the condenser principle to produce a current which, until a better nomenclature is established, is termed for temporary convenience of identification, the "electric wave current." This is, in reality, the subjection of the patient's entire person to the influence of powerful condenser waves. The patient thus forms, as it were, one plate of a very large condenser (its effect may be greatly intensified by making an independent connection to a near-by insulated and large sheet of metal). I have published and described both currents fully elsewhere.[1]

The specific work done upon tissue, in the treatment of chronic rheumatism, that is to say, the metabolic exchanges effected, are those amply demonstrated by Professor d'Arsonval, of the College of France, in his laboratory, and by Drs. G. Apostoli and Berlioz in actual practice and observation upon their patients. To these observations the writer has also contributed frequently. These effects upon the patient may be briefly outlined as follows:

1. (*a*) A total absence of action on sensation (d'Arsonval and Tesla effects); (*b*) a minimum primary effect upon sensation and a rapidly produced benumbing effect (Morton currents).

2. (*a*) Failure to excite muscular contractions (d'Arsonval and Tesla effects); (*b*) comparatively painless muscular contractions and gradual benumbing of the neuro-muscular mechanism (Morton currents).

3. Promotion of metabolic exchanges based upon the experiments of d'Arsonval. (*a*) Respiratory combustion; the oxygen absorbed is increased and the carbon dioxide eliminated is greatly augmented; the elimination of H_2O is also greatly augmented; (*b*) the urea is increased in quantity, while the proportion of uric acid to urea becomes normal.

4. The heat production is increased.

5. Loss of weight occurs during applications, but between applications the weight again increases.

6. Vasomotor action is influenced; the blood pressure at first becomes lower, and finally rises to a stationary point.

The increased combustions amount to from thirty to fifty per cent. Professor Rienzi, of Naples, has recently demonstrated that fifty per cent. more neutral sulphur is oxidized by these currents, and that there is a decisive effect upon the metabolism of nuclein.

---

[1] Paper read before the Section on Medicine of the Academy of Medicine, March 20, 1900.

[1] New York MEDICAL RECORD, April 2, 1881. New York MEDICAL RECORD, January 24, 1891. New York Electrical Engineer, March 2, 1899. Bulletin Officiel de la Société Française d'Électrothérapie, January, 1899.

The theurapeutic effect of this increase in the nutritional activity of the patient's organism is a progressive and rapid return of general health. He sleeps, eats, works, and feels better; his normal secretory and excretory functions return; soon in ratio with the improvement in his defective nutrition his local disorders in turn improve, and the improvement is permanently progressive because it is built upon the sure foundation of the removal of a defective general malnutrition. Such is the fundamental basis which I have long maintained is the one most efficacious in modern medical science for the treatment of numerous chronic diseases, and in no disease more applicable than in rheumatism.

These currents should be and can be also applied locally. Moreover, in the local treatment of arthritism, we must not neglect the spark, our ancient ally of the static machine. The long, clean percussion spark, administered to a rheumatic joint, sets up within the tissue a commotion or perturbation of the physical tissue particles, a sort of maladjustment of tissue particles, followed at once by readjustment. We may speak of it roughly as a sort of molecular gymnastics, impossible to accomplish by any other means. As a result of this treatment, the joint assumes a new and healthful nutritional activity.

In another form of spark treatment ("the friction spark") an electrode is rubbed over the skin with the clothing intervening, and produces a hot, burning feeling; it excites all nerve end organs and delivers to spinal and other centres through the afferent nerves the peripheral impression, and thus produces, as has been abundantly proved by laboratory experiment on the lower animals, changes in the central nerve cells, even to the extent of modifying their microscopical structure (Hodge). Secondly, as to rheumatism: Clinically and for purposes of treatment we may divide rheumatism and its allied diseases into (1) muscular rheumatism; (2) rheumatism, acute, subacute, and chronic; (3) gout; (4) rheumatoid arthritis.

There are not wanting many and excellent authorities, who regard all forms of rheumatism as a manifestation of a disorder which has its primary seat in the nervous system. A defect in the neurotrophic nerve mechanism may well cause a defective metabolism with excess of uric acid and consequent affection of fibrous tissues by uric-acid deposit, or, indeed, in some forms of arthritis, affect primarily the nutrition of the joint structure. This general view, at present, is as good as any other, and affords a working basis for the therapeutic use of electricity.

Thirdly, as to the application of the foregoing principles to the treatment of rheumatism: There is at the present time a prevalent movement in favor of general electrization of the patient, whether by the alternating electric current bath of Gautier and Larat, by the high potential, high frequency autoconduction and inductive or direct methods of d'Arsonval, or by the electrostatic and electrostatic-current methods which I have long advocated. The reason for this is obvious. Most chronic diseases are constitutional, general, and diathetic. Undoubtedly gout, and many if not all forms of arthritis, may be so considered. Certainly no one will deny that in most cases of rheumatism we have two aims in view—one to treat the diathesis, the other to treat the local manifestations. Of what use is it to treat the affected joint alone and neglect the diathesis? It is like putting a new patch on an old garment. The new patch will tear out.

At this point I feel that my paper is practically concluded, for the application of the foregoing principles is a simple matter, though implying, of course, some technical skill, patience, and, may I add, enthusiasm. I will, however, briefly apply these principles and methods in practice, first adding a few words as to technique.

Technique.—1. The Static Induced Current: This current is fully described in textbooks, and is familiar to all who use influence machines; it, therefore, needs no description here.

2. The "Electric Wave Current" (temporary nomenclature): A powerful influence machine must be employed for this as well as for all currents and sparks. The accompanying diagram illustrates the connections necessary to produce this form of high potential current.

The electrodes may be of any pliable metal. I use block tin rolled out into fairly thin sheets, and cut off electrodes of any suitable shape. I buy a few dozen brass binding-posts and attach one to each electrode. A spinal electrode is one inch by twelve inches. The same strip serves to wrap around joints or for many other local applications. Sometimes I encase an entire arm or other member in a metallic mould. A flat plate, say a foot square, may be laid upon the chest, abdomen, back, or elsewhere. When a strictly local effect is desired, the smaller the electrode the more intense the local action.

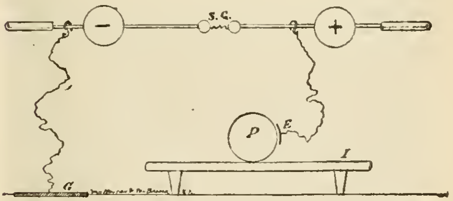

FIG. 1.—*I*, Insulated platform; *P*, patient; *E*, electrode; *G*, ground connection; *S. G*, spark gap.

In place of block tin I often use metallic cloth (such as military furnishing-shops sell) cut into bandages. With such bandages I bandage a leg or arm, or, indeed, as is quite easily done, the whole body, thus enclosing the patient's entire person in a complete metallic suit of clothing; or a metallic cloth shirt or jacket and trousers, resembling a suit of pajamas, may be quickly made and worn by the patient for the purpose of treatment. It will be noted that the bare metallic electrodes lie against the bare skin. They require no moistening. If at first, for a moment, there are points of prickling sparks, slight pressure will dispel them. However the metallic electrode may be applied, the patient's electric position is that of one tinfoil coating of a Leyden jar, whose other tinfoil coating is represented by the walls of the room and neighboring objects and the ground connection, while for dielectric or insulation the air of the room corresponds to the glass of the jar. That a condenser effect is truly established may be noted by observing that under the circumstances of administration described the spark crossing the spark gap changes its quality exactly as when ordinary Leyden jars are added.

As to the kind of rheumatism, all cases receive from fifteen to thirty minutes of the wave current, to meet the general and diathetic requirements. The duration of a treatment must be decided by the effect upon the patient, exactly as one would prescribe the duration of a ride upon horseback or other physical work. If the patient feels tired and exhausted, the treatment has been too long. The next treatment can be curtailed to a point where it ceases short of weariness. Often the general treatment is given by applying the pliable electrodes to one or more joints, thus combining the local and the general treatment.

3. The Spark: This has been fully described, and is well understood.

Special Applications.—1. Muscular Rheumatism: As has long been known, the application of sparks, at first gently and gradually increasing, will invariably, in a single treatment, relieve the pain and soreness of the muscles, and permit of their free motion. The symptoms return after twelve to twenty-four hours, and are again treated with the same results, the duration of relief being continuously lengthened until in a few days to a few weeks, according as the case is acute or chronic, a cure is effected.

2. Rheumatism—Subacute and Chronic: The treatment is in general as described; then local by long powerful sparks or by a local application of the wave current or the static induced current. I have continuously used some form of electrostatic treatment for rheumatic affections for twenty years, both in an almost continuous dispensary practice and in private practice, excluding for testing purposes every form of medication. I hope some day to collect and publish the cases. I can here only say in general that of every form of treatment I have tried, I have found none in any way comparable for relief and cure to the electrostatic.

3. Gout: More especially will the above remarks apply to gout. In the acute local attack I at once wrap the joint in a metallic cloth bandage or encase it in a pliable metallic mould, and give the wave current, or, if one chooses, the static induced. Time and again, a limping, suffering patient has walked off after treatment, with a firm tread, stamping his foot on the floor to assure himself that the pain had truly left him. Often the relief is permanent; often again it is only temporary, and requires a number of treatments to make it permanent, for often the gouty attack may be but an œdema, and again it may consist of a profuse deposition of the sodium biurate. In gout also the general treatment is indicated upon the most positive basis of producing the increased metabolic exchanges, fully alluded to.

4. Rheumatoid Arthritis: In regard to this disease, I have little to add to what I have written in the Medical Record of December 9, 1899, and to the general presentation of results obtained in my hospital dispensary work, described by my assistant, Dr. W. B. Snow, in the *Post-Graduate* of November, 1899. This I will say here, namely, that the progress of this disease in any stage may be completely arrested; if in an early stage, very promptly (say a month); if in later stages, with more difficulty (say in from three months to a year).

For instance, a recent patient, with many joints profoundly affected, came to me for treatment: first, in ten to twenty days free motion of the cervical vertebræ returned, then a free motion of the lower jaw with no further grating sounds, then free movement of one affected hip-joint—these were all recent invasions of the disease, and merely proved that the earlier the stage is treated the quicker are the results. In the same patient, other joints, now affected for five years, progress toward recovery much more slowly. In this disease, the long spark applied to each individual joint affected seems to me to be essential in establishing a new joint nutrition.

I may say here that my convictions as to the efficacy of electrostatic treatments are, in the first instance, based upon dispensary practice, in which no medicine is added to the electricity. But in private practice I put all my rheumatic patients upon a meat diet, because in their usual condition it is more nutritious and more easily digested, and in rheumatoid arthritis I have believed that ten drops of iodide of potassium, three times daily, with much water and after meals, and arrived at by increasing from one drop upward to the ten, is of assistance in treating the case.

In conclusion, I wish I could impress upon those who can control hospital work for the treatment of chronic diseases, especially arthritism, what a fruitful field for labor they have before them in the intelligent use of electrostatic administrations. In my opinion, a good influence machine—the most powerful that can be obtained—should constitute a part of the equipment of every hospital in the land. For while diagnosis, prognosis, and pathology are the letter of the law, we may yet remember that therapeutics is the good Samaritan.

The Closure of Abdominal Wounds and Hernial Openings by Means of Buried Silver-Wire Net (Healing in of Filigree Pads).—O. Witzel believes in the efficacy of buried filigree pads for protection against the development of abdominal ruptures and for the avoidance of recurrences. The wire of these pads is heavy. The diameter of the buried net should be at least three times as large as the hernial opening. The neighborhood of the femoral vein makes operation on femoral herniæ somewhat difficult. The wounds should be closed by suturing the separate layers of tissue one by one.—*Centralblatt für Chirurgie*, March 10, 1900.

Hæmogastric Infection in Yellow Fever.—Carlos J. Finlay revives this ancient term, and applies it to the form of yellow fever marked by gastric or intestinal hemorrhage. He suggests that this form is a mixed infection with a bacillus of the colon group—bacillus *a* of Sternberg or the colon bacillus, or not improbably the bacillus icteroides of Sanarelli (hog-cholera bacillus?), the latter acquiring pathogenic properties for man through association with the yellow-fever germ, whatever that may prove to be. The black vomit is therefore a sign of secondary infection. This occurs in three varieties of cases: (1) In the superacute cases in which we have a simultaneous infection with the hæmogastric germ and the yellow-fever germ, the former having already acquired pathogenic properties through previous association with the latter. (2) In the more common cases in which black vomit appears on the fourth or fifth day, we have a secondary auto-infection with a bacterium, pre-existing in the gastro-enteric tract or introduced there as a saprophyte, which becomes suddenly pathogenic. (3) In cases in which the black vomit appears suddenly in apparent convalescence from a benign attack. Here there is probably a reinfection with a new and malignant virus mixed with the hæmogastric germ.—*Revista de Medicina y Cirugía de la Habaña*, March 10, 1900.

The Double Products of the Parasitic Fungus of Human Cancer and of the Nectria Ditissima Parasite of the Cancer of Trees—the Physiological and Therapeutic Action of Nectrianin.—Bra and Mongour in experimenting with these substances found that the soluble products of the cultures of the parasitic fungus of human cancer have the same effect as, only more powerful than, the triturated liquid taken from the neoplasm. Nectrianin, though analogous in its action, is still more powerful than either. It has little or no effect on healthy animals, but in cancerous animals and in the human being suffering with this dread malady, its injection in doses of 5 c.c. several times a week is followed in a few hours by elevation of temperature from 1° to 3°. An increased dose is followed by chills, accelerated pulse, thirst, and headache. The crisis comes at the end of several hours with perspiration, polyuria, and profound sleep. It is certain that treatment by nectrianin has improved the local condition of patients—has arrested or diminished the hemorrhages, suppressed the fetid discharges, and has shown a tendency to cover the growth with epidermis. It cannot be called a specific remedy for cancer, but it has certainly ameliorated the condition of the patients. This therapeutic measure may well be combined with surgical treatment.—*Journal de Médecine de Bordeaux*, February 25, 1900.

PERNICIOUS ANÆMIA AS A CHRONIC INFECTIOUS DISEASE.

BLOOD impoverishment may obviously result from a number of causes, and the cellular elements and the hæmoglobin may be affected variously. Far too little is known concerning changes in the plasma. In accordance with the etiological factors a classification of cases of anæmia into primary and secondary has been proposed, and in accordance with the relations between the hæmoglobin percentage and the number of red blood corpuscles and with morphological variations in the latter, together with the general clinical symptoms, attempts at subclassification have been made, but in neither instance with entire success. Although considerable advance has been made in recent years on the subject of hæmatology, a good deal is yet to be learned with regard to diseases of the blood. Among the most interesting and the most important of these is that form of anæmia designated by Addison as "idiopathic," and since known also as "essential" and "pernicious." Although, according to Addison, the disease arises without discoverable cause, it cannot be concluded off-hand that it is therefore a primary or independent disorder. Careful studies by William Hunter pursued for a long time would seem to show that in some cases at least the disorder may occur as the result of intoxication from the gastro-intestinal tract.

In a recent communication on this subject Hunter (*Lancet*, January 27, February 3 and 10, 1900) reviews his previous work and makes some additional observations. He had already determined that the pathological changes of pernicious anæmia are highly distinctive and indicative of excessive blood destruction as the characteristic feature of the disease; and that the latter is probably dependent upon the action of a certain special blood poison derived from a specific infectious process in the gastro-intestinal tract. Observations directed to the discovery of the nature and the cause of the infection indicate that it is not dependent upon general, but rather upon special conditions. Attention is called to the frequency with which an unusually cario-necrotic condition of the teeth is encountered in cases of pernicious anæmia as an antecedent to the onset of the anæmia; the frequency of the conditions of glossitis and stomatitis among the first objective symptoms of the disease, and sometimes as the first subjective and objective trouble; the frequency of gastric symptoms (sickness, retching, vomiting) pointing to gastric trouble; the presence of gastric catarrh of an infective nature in pernicious anæmia; the origin of infective gastric catarrh from necrotic and suppurative teeth; and the conclusion that in pernicious anæmia the original infection underlying the disease is in most cases to be traced to the teeth and possibly in a few cases to exposure to drain-poisoning.

As a result of observations made in seven cases and of an analysis of the literature, Hunter reached the conclusion that pernicious anæmia is a special form of chronic blood poisoning—a toxæmia—the result of a special infection of the digestive tract, especially of the mouth and the stomach, and probably, although to a less degree, of the intestine. The chief source of infection is through the mouth from long-continued and neglected cario-necrotic conditions of the teeth, and sometimes possibly from stomatitis arising from other causes. The usual effect of this infection is a chronic infectious catarrh of the mouth and stomach which may in time lead to deeper-seated changes, *e.g.*, ulcers of the mouth and tongue, chronic glossitis and atrophic changes in the tongue, and chronic gastritis with atrophy of the gastric glands. Evidences of the infectivity of the micro-organisms of dental decay are overwhelming, and in suitable cases the infective nature of the resulting catarrh of the stomach can also be demonstrated. The infection is chiefly streptococcal, and probably derives its special character from being of a mixed character. Such infection occurs the more readily if the stomach or the intestine is already the seat of disease from any cause. The gastric and intestinal irritation (sickness, retching, vomiting, looseness of the bowels, and diarrhœa), so often noticed, and which is even more common than is generally stated (being observed in almost eighty per cent. of cases), is the local effect of this infective catarrh, while the excessive destruction of blood taking place in the portal area is the result of the action of the poisons in the blood. The fever so commonly encountered is not an accidental occurrence, the effect of weakness, but is a feature of the disease, a result of the infective process itself, and its variations correspond to variations in the activity of the process. Such variations are common, occurring from week to week, sometimes from day to day, in the development of the disease, even when it is pursuing a fairly progressive course. In addition, however, the advance of the disease toward a fatal termination is often marked by one, sometimes by two periods of marked improvement, lasting, it may be, many months or a year or more, and followed by relapses. This character of the disease is regarded as the result of a relative immunity, unfortunately only temporary in nature, conferred by the disease itself—an immunity accelerated and greatly strengthened for a time by suitable medicinal treatment, notably by administration of arsenic.

The foregoing conclusions suggest certain new considerations in regard to treatment, of which the chief are minute attention to the hygiene of the mouth and especially of the teeth, with the immediate removal of every source of infection there; stricter antiseptic treatment of the stomach and the intestines; and antitoxic serum treatment with the view of antagonizing within the blood itself the poisons absorbed into it.

AURAL MANIFESTATIONS OF LEUKÆMIA.

Deafness is not an uncommon symptom of leukæmia. It may appear early and has been attributed to hemorrhage. Nausea and vomiting also may occur early. Vertigo and headache are sometimes present, and syncopal attacks may occur. An interesting case in which symptoms of acute Ménière's disease, or aural vertigo, were observed in a patient suffering from spleno-medullary leukæmia was reported by Weber at a recent meeting of the Royal Medical and Chirurgical Society. The patient was a man thirty-one years old, with advanced leukæmia and a history of a malarial fever six years previously, who presented great enlargement of the spleen and the liver. Death resulted from collapse following internal hemorrhage. During life ophthalmoscopic examination disclosed the presence of so-called leukæmic retinitis. About six months before death acute aural symptoms set in, namely, headache, vertigo, and vomiting. Examination indicated a leukæmic affection of the internal ears, and marked deafness developed within a short time. On post-mortem examination a portion of the scala tympani and the perilymphatic spaces of the semicircular canals were found filled with newly formed fibroid and bony tissue. The scala vestibuli, the canal of the cochlea, and the vestibule presented only comparatively slight changes. The nerve trunks exhibited no obvious alteration.

A study of similar cases reported indicates that the pathological appearances presented by the internal ear after death differ in different cases, partly in accordance with the length of time that has elapsed between the onset of the acute aural symptoms and death. In most cases the post-mortem appearances suggested that the onset of aural symptoms (vertigo, headache, vomiting, and deafness) marked the occurrence of more or less extensive extravasation of blood into the semicircular canals and the cochlea, the process being doubtless nearly always more or less symmetrical and simultaneous in the two ears. In such cases, although apparently lymphocytic infiltration and hemorrhages may be found in various parts of the ear after death, the labyrinthine hemorrhage is probably the essential lesion responsible for the acute aural phenomena. Subsequently, vascularization and organization proceed in the usual manner, the clot becoming gradually replaced by newly formed connective tissue, connected closely by its blood-vessels with the endosteum of the bony labyrinth. In the course of time, should the patient live long enough, more or less ossification occurs in the newly formed tissue, and irregular processes of bone project inward from the walls of the bony labyrinth. At this stage of the pathological process transverse sections of the bony semicircular canals generally show the membranous canals surrounded by a meshwork, or by irregular masses of newly formed bone and fibroid tissue completely filling up the perilymphatic spaces.

In addition to the cases presenting acute apoplectiform aural vertigo there occur also cases with aural troubles of a less severe or less sudden nature. In these the symptoms may be in part wholly independent of the leukæmia, but in part due to small hemorrhages and patches of lymphocytic (leukæmic) infiltration in various parts of the auditory apparatus.

At the same meeting Mott related a somewhat similar case. A man thirty-eight years old, who had been in poor health for two years following an attack of influenza, was seized six months before coming under observation with sudden pain in the left side of the abdomen, and a little later with pain in the head and deafness, with loss of power of maintaining equilibrium. The deafness came on suddenly, first in the left and then in the right ear. The patient was a little cyanosed, the temperature 97° F., the abdomen distended, the liver, spleen, and lymphatic glands enlarged. The hæmoglobin estimation was fifty-four per cent., and the leucocytes were enormously increased, almost equalling the red corpuscles in number. The muscular powers of the patient were good, and there was no loss of co-ordination in the arm, but he could not balance himself in walking, and could not stand at all with his eyes shut. The knee jerks were absent on both sides. Vision was imperfect; accommodation was good, but the reflex action of the right pupil was sluggish. The fundi showed slight changes. Hearing improved considerably. Taste and smell were normal. After seven days the man was found to be stone-deaf in both ears on waking in the morning, and three days later he died in coma. Upon post-mortem examination the liver was found to weigh 5.5 kgm. and the spleen 1.8 kgm. The brain was congested and the seat of hemorrhages. The petrous bone was soft and friable from rarefaction. The spinal cord and nerves exhibited no alteration. There was hemorrhage into the posterior spinal roots and into the cochlea. The hemorrhage into the semicircular canal accounted for the loss of equilibrium. This and the deafness were accounted for by hemorrhage into the cochlea and labyrinth.

TREATMENT OF ACUTE LOBAR PNEUMONIA.

It is now generally conceded that micro-organisms play an important part in the causation and progress of pneumonia, and consequently the disease must be given a place among the infectious maladies. The investigations of Klebs, Friedländer, Fränkel, and Sternberg have quite definitely settled this point. Therefore it would seem that the time has come for new methods of treatment to be put into practice. It used to be the invariable custom to bleed freely and to administer heroic doses of antimony to all sufferers from this complaint. This was the routine treatment in every principal medical school of the world. Hughes Bennett was the first English-speaking physician to point out the defects of this treatment, and he published statistics some years ago showing that medical interference did very little toward the cure of the complaint. Balfour, of Edinburgh, at the time when that school was a veritable stronghold of the antiphlogistic methods, went to Vienna and was astonished to find that Skoda gave those under his care who were attacked by pneumonia nothing but hay tea, and moreover obtained better results than did the Edinburgh physicians. Ultimately venesection and the giving of large doses of tartar emetic were almost entirely abolished, although many eminent authorities believe that in certain cases both blood-letting and antimony are of decided benefit. Sir Hermann Weber says: "The prejudice against the use of small doses of antimony and against bleeding in moderation in suitable cases is entirely unfounded. Sir Samuel Wilks and Sir William Gairdner are of the same opinion. Dr. Edward F. Wells, at the last meeting of the American Medical Association, spoke of the efficacy of venesection in plethoric persons, and considered that in these cases the procedure had no satisfactory substitute. He also recommended a simultaneous subcutaneous injection in the chest of decinormal saline solution or the use of an enema of the salt to replace the quantity of blood withdrawn. Dr. Hobart A. Hare at the same meeting said that he believed that the abortive treatment by venesection, aconite, and veratrum viride was applicable only in a few vigorous cases. Sir William Broadbent opines (*Practitioner*, March) that "in a large proportion of cases it cannot be said that the regular administration of medicine of any kind is necessary, but it is usually a comfort to the patient and friends to have the feeling that something is being done."

In regard to the germ theory of pneumonia, and referring to the investigations of scientists to establish its correctness, Dr. Pye-Smith, in "Allbutt's System of Medicine," says: "While recognizing the interest and importance of these laborious researches, we must observe that even the diplococcus of Talamon and Fränkel does not fulfil Koch's three tests of a pathogenic organism; as they are fulfilled, for instance, in anthrax, relapsing fever, and tuberculosis. It is not invariably present in the tissue of pneumonic lung; it does occur in other situations in health when injected as a pure cultivation; it does not always reproduce itself and cause a fresh case of hepatization of the lungs. Nevertheless the frequency of its occurrence and the fact that it often reproduces the disease by inoculation make it probable that it plays an important part in the natural history of pneumonia." Dr. Andrew H. Smith, in his exceptionally able monograph on the subject in the "Twentieth Century Practice of Medicine," vol. xvi., believes that pneumonia is not an inflammation of the lung, for the reason that in his opinion it does not affect the nutrition of the organ, but is a process of germ culture in which the pneumococcus grows in a culture medium supplied by the functional capillaries of the lung. The majority of writers do not agree with Dr. Smith in this view. Dr. James K. Crook, in *Medicine*, April, thus expresses his opinion on the matter: "From the author's study on the subject, he would fully agree with Dr. Smith that the process is one of germ culture, but it may also be as properly described as an inflammation, as are the conditions set up by the same microbe elsewhere, viz., in the pericardium, the pleura, and the joints. It is, of course, a special form of inflammation produced only by special forms of micro-organism and not analogous to inflammations elsewhere, because the lung itself has no analogue elsewhere in the body." Time, however, alone can prove whether Dr. Smith is right or wrong.

In the mean time the question before us is whether the knowledge that acute lobar pneumonia is an infectious disease has afforded any firm grounds for the hope that it may be possible to abort the disease. Again on this point there is a great divergence of opinion. Most authorities hold that such an expectation is not justified by the extent of our present knowledge. Dr. Smith, with many others, thinks that this may be done, and argues that therapeutic efforts should be directed to the arrest or inhibition of the germ culture from which the diplococcus obtains its nourishment. He claims that inasmuch as this culture medium is derived from the blood, any substance added to the latter will also be found in the former, and if that substance is inimical to the growth of the coccus, it will in so far act in the direction sought. The fact that the pneumococcus is the most vulnerable of the germs is in favor of this argument. Creosote, calomel, quinine, and salicylate of sodium are the drugs possessed of germicidal properties best calculated to produce the desired effect. Leaving out of the question the three former drugs, we will briefly consider the use of salicylate of sodium in the treatment of pneumonia, as demonstrated by the experience of some who have witnessed its effects. Sir Hermann Weber, in *The Practitioner*, February, writes as follows: "Salicylate of soda was tried in quantities of gr. xx. to xl. per day at the German Hospital, London. The effect was quite satisfactory on some persons in diminishing the pyrexia, the pleuritic pain, the thirst, the dry heat of the skin, and perhaps also slightly the duration of the acute stage, but scarcely sufficiently marked to be quite sure. In other persons the excessive perspiration produced by the remedy, and the noise in the ears, rendered this treatment disagreeable; the most objectionable effect, however, on some persons was excessive headache, and on some others the appearance of blood and albumin and casts in the urine, so as to oblige us to stop the remedy. Although it cannot be denied that in some cases the salicylate acted beneficially, it produced, as just stated, in others unpleasant and in some even injurious effects." Pye-Smith refers to the use of the salicylates in these words: "Salicyl compounds are only indicated when pneumonia occurs as a complication of rheumatism." Dr. de Becker recommends salicylic acid for acute pneumonia (*Annales et Bulletin de la Société de Médecine d'Anvers*, March and November, 1898), and believes that if administered at an early stage of the disease it is a sure preventive. Eleven out of twelve patients treated thus by him were quickly cured. He has also noted that the expectoration after the use of salicylic acid becomes liquefied, and is of the opinion that in the giving of the drug the expectoration should be the guiding symptom. Debility and heart disease should contraindicate this treatment. The most favorable reports of the action of salicylate of sodium come, one from Austria and the other from this country. The first stated that a series of seventy-two cases of pneumonia occurring in Austria had been treated with large doses of sodium salicylate, gr. cxx. daily. All of these patients had recovered, and in not one had the disease terminated by crisis. The second report was published in the MEDICAL RECORD, April 22, 1899, by Dr. Sebring, of Kingston, N. Y., and deals with seventy-five cases of pneumonia treated with gr. cxx. daily of the same drug, with the result that but one patient died. Dr. Sebring also says that out of one hundred and twenty-five cases of pneumonia treated with salicylate of sodium in his neighborhood only one proved fatal. Of course these results are magnificent, and if the drug should be found as effective after a more extended trial the problem of how best to treat acute lobar pneumonia will be solved once and for all. Until its use has been more widespread than is at present the case it will be as well to express no pronounced opinion as to its curative properties.

Investigators have not as yet succeeded in preparing a reliable antitoxin for pneumonia, although de Renzi has used the serum prepared according to Pane's instructions since 1896 in grave cases of pneumonia, and states that his former mortality in such cases of twenty-four per cent. fell under the treatment to nine per cent. The data at present available do not warrant us in arriving at a definite conclusion as to the value of this treatment. A great step in advance has been made in establishing the microbic origin of lobar pneumonia, and it behooves us patiently to await the discovery of the most effective means of meeting the attacks of those pathogenic organisms responsible for the condition. There has been up to the present time no sufficiently strong reasons brought forward for altering the existing expectant methods of treatment.

THE CRAIG COLONY FOR EPILEPTICS.

DR. FREDERICK PETERSON, of this city, some years ago thus described what in his opinion is the best manner of treating the epileptic: "There is but one kind of institution which can meet the case of those who suffer from this disease. No asylum, no large hospital, no single vast building in a great city is appropriate for the purpose. It must be an establishment combining many unusual features. It must have schools and teachers for the young epileptic. It must have offices, shops of all kinds, stores, dairy, farm, gardens, granaries; for, as they grow up, these patients should acquire trades or professions. It must have a group of small hospital and asylum buildings, where such as are sick or mentally infirm may be cared for. It must have skilled physicians. It must have a church, amusement hall, gymnasium, and bathing establishment. It must have finally a pathological laboratory presided over by the keenest pathologist obtainable, so that in course of time a cause and cure may be discovered for this terrible disease. Such a place would not be a hospital in the ordinary sense of the term. It would be a village in itself, a colony for epileptics."

Mainly through the exertions of Dr. Peterson himself his ideal institution became realized, and Craig Colony, founded and managed upon the lines indicated in his sketch, was established. The results so far of treating epileptics by these methods have been eminently encouraging, and the prevailing belief that detrimental effects would ensue from the close association of patients has been proved baseless. Moreover, viewed from a practical and economic standpoint, ample justification has already been afforded for the establishment of the colony. Dr. Spratling, the chief executive officer, says there is every reason to believe that the value of manufactured and home products will ultimately reach seventy-five per cent. of the entire cost of maintenance. The sixth annual report of the board of managers states that "there have been received into the colony since its opening, February 1, 1896, five hundred and four epileptics, of which three hundred and seventy-eight remain. The buildings nearly completed and those in course of construction will increase the capacity of the colony to a total of seven hundred and twenty beds. . . . There will still be urgent need for dormitories, when the buildings now under construction are completed, particularly for an infirmary for each sex." In the report of the medical superintendent mention is made of the great urgency of securing money apart from maintenance for the purpose of scientific research, and the same report, referring to admissions and discharges, states that at the time of presenting the report a year ago there were three hundred and twenty-two colonists under care; during the past twelve months this number was increased by admitting ninety-five new cases; while during the same period thirty-nine were discharged, either as recovered, unimproved, died, or transferred to some other institution, leaving three hundred and seventy-eight—a total gain of fifty-six during the year, a number limited entirely by lack of room for a larger number. With regard to treatment and results the report says: "The good results to the colonists of the various forms of treatment have been more general and far more apparent during the past year than any year in its history. Collectively they have derived vast benefit, while many of them have become important factors in the colony's daily life." The results in treatment are summed up as follows: "First, in cures effected; second, in the very marked and general reduction in the number and violence of seizures; third, in the great physical improvement, often amounting to a complete physical regeneration, in large numbers of cases; fourth, in the steady growth and development of the idea of colony life; fifth, in the marked increase in the ability and number of colonists to become fixed and useful factors in the colony's everyday life."

Craig Colony and kindred institutions have brought into evidence the fact that the rational manner to treat epilepsy is not as heretofore by confining its victims in asylums and by drenching them with drugs, but by giving them the opportunity of regular exercise and open-air work. Industrial and physical training performed under healthful conditions and intelligently directed will undoubtedly result in improvement to the epileptic.

THE NEGRO QUESTION.

The abolition of slavery, instead of exercising a favorable influence upon the negro morally and physically, would rather appear to have had a contrary effect. The physical degeneracy of the Afro-American race yearly becomes more and more evident, while it is to be feared that the moral condition of the colored man in this country is at a lamentably low ebb. The cause of this retrogression is variously explained, the most popular theory being that it is owing to the sudden alteration in the mode of life which took place after the Civil War. It is argued, and with much show of reason, that the negro ought not as yet to be regarded as altogether responsible for his actions; that, when freedom came, he resembled a child who had not learned to take care of himself, and consequently plunged unthinkingly into vice and dissipation without counting the cost. Other students of the negro problem take a much sterner view of the case, and attribute the black man's sins to inbred viciousness. Of this number is Dr. Paul B. Barringer, of the University of Virginia, who gave an address on the subject before the Tri-State Association of Virginia and the Carolinas in Charleston, S. C., on February 20th. After referring to the cannibalistic propensities of the West Coast African negro of the present day, Dr. Barringer speaks of the American negro as follows:

"Thirty-five years have passed since the negro changed from the condition of a slave to that of a freedman. In every part of the South, it is the opinion of every man of unbiassed mind that the second generation is infinitely worse than the first. So patent is this that I would be tempted to doubt the sanity of any man, having fair opportunities to judge, who declared the reverse to be true. The question for us today, then, and the question of questions for the South is, 'What is the cause of the change, and what can be done to remedy the evil?' The first thing is to seek out the truth, however unpalatable it may be, and in my opinion it is very simple: The young negro of the South, except where descended from parents of exceptional character and worth, is reverting through hereditary forces to savagery. . . . Everything points to the fact that the phylogeny of the negro is carrying him back to barbarism; that the temporary elevation produced by the discipline of slavery is not being maintained by the efforts we have made at common-school education in the hands of his own race, and that we must at once, if we would save the negro and the South, try something else. I would finally urge that we try henceforth an education of trade or industrial type, given at the hands of well-chosen white teachers, who will teach him to respect, to obey, and to work. Under this, if experience be not fallacious, he will improve in morality, in character, and in capacity as a taxpayer."

This is the judgment of an educated Southerner in regard to the negro question, looked at from the moral standpoint, and as such is entitled to the close attention of thinking men. The Medical Record has many times called attention to the physical deterioration of the colored race on this continent, clearly owing to the insanitary conditions in which its members live. The matter is of the most serious importance, and yearly assumes a more ominous aspect. It is certain that steps must be taken to relieve the present situation.

SILVER WIRE AS SUTURE MATERIAL.

Silver wire is a material which has been used for a long time more or less extensively for suturing, and the qualities which have recommended it especially are strength, ease of sterilization, and permanence. These are obvious qualities, but only the second does not include some disadvantage. The disadvantage of great strength, perhaps small, consists in the fact that it is very easy to draw sutures of such material too tight, and thus cause tension which will give rise to a certain amount of tissue necrosis, no matter what the tissue. Furthermore, great strength in suture material is apt to make us depend too much on force to maintain apposition of surfaces, and to cause us to forget that the function of a suture is to keep surfaces in contact until cicatrization is well advanced or complete. Force does not assist this process. Permanence in a suture material does not appear entirely an advantage, but rather an unfortunate quality in a substance otherwise desirable. After a wound is completely healed, a suture remaining in the tissues is no longer a suture, it is a foreign body. In one of our prominent institutions, the Johns Hopkins Hospital, the use of silver wire is very general, and in a recent publication (1899), Johns Hopkins Hospital Reports Nos. 5 to 9, a series of operations for the radical cure of hernia, chiefly inguinal, is presented. The suture material for the superficial parts of the wound as well as the deep aponeurotic structures was, in this series of nearly three hundred cases, practically always silver wire, and the primary results in the wounds were almost invariably good. It has also been a frequent practice in that hospital to cover the completely closed wound with silver foil, copper foil having been tried and found irritating. When either of these metals was used in this way, it was found that its contact with the skin and the wound exudate produced actual antiseptic effects from the small amounts of metallic salts thus generated, and we are able from this experience to infer that silver wire used subcutaneously behaves in the same way. This quality, while useful in the foil covering the skin wound, is of no advantage in a suture entirely buried, for there is no difficulty in sterilizing silver wire, and there are no colonies of bacteria under the skin, as there are in it, to require post-operative attack with an antiseptic. We cannot think that silver wire is the suture *par excellence* in operations for hernia on account of its permanence, because the final result after these operations does not depend upon the firmness with which the aponeurotic and muscular structures are held together, but upon the completeness and promptness of the cicatrization, and the accuracy of apposition. Consequently non-absorbability is not an advantage and may be a distinct disadvantage. It is well known that non-absorbable foreign bodies may remain harmlessly under the skin for long periods, and then for some undiscoverable reason begin to cause trouble. Many of these Johns Hopkins cases have apparently carried their silver sutures for many months without annoyance, and may continue to do so for many more, but this does not alter the fact that future trouble is possible for them, even if improbable, something which is avoided if an absorbable suture is used. The difficulty of securing and sterilizing satisfactory absorbable sutures is familiar enough, but cannot be logically urged against the suitability of the suture when we have it properly prepared. We know that it is possible to get a sterile absorbable suture if we are careful enough, and we know also that such a suture is more desirable than one which remains in the tissues. We may, then, fairly conclude that a complete case is not made out for the silver suture, while the properly prepared absorbable suture seems unassailable.

STATE HOSPITAL FOR CONSUMPTIVES.

The universally recognized methods of treating pulmonary tuberculosis nowadays are by the common-sense ones of fresh air and diet. This mode of treatment is, however, by no means new, but was known and practised ages ago. The beneficial effects of an open-air life as a remedy in consumption is perhaps as old as civilization itself. Hippocrates' views on the matter would probably differ but little from those held by the foremost exponents of the modern sanitarium system. The Romans, too, had pronounced opinions as to the efficacy of fresh air in the treatment of phthisis. To the Germans belong the credit of introducing the isolation methods now in vogue everywhere, combining exposure to the open air with enforced diet. Dr. Brehmer, whose establishment at Goerbersdorf was founded in 1844, was undoubtedly the pioneer in this movement. His example has been largely followed in Germany, America, and elsewhere.

But these institutions are one and all for the benefit of persons in easy circumstancs. Up to quite recent times, says Dr. Goghill, writing in *The Nineteenth Century Magazine*, February, 1899, "no attempt has been made on the European continent, and, it may be added, nor in this country, to provide like resorts for the necessitous. In Great Britain, on the other hand, the position is reversed. No private sanatoria have existed until quite lately, but consumptive hospitals for the poor and needy have existed for long periods, and to them is probably due the remarkable decrease in phthisis that has taken place in England since a date corresponding to their establishment. Among the principal consumptive hospitals in Great Britain are Brompton, founded in 1841, 321 beds; Victoria Park in 1848, 164 beds; North London in 1860, 78 beds; The City Road Hospital in 1863, 75 beds; and the Royal National Hospital in Ventnor in 1869, 138 beds." It must, nevertheless, be understood that, although these establishments are solely for the benefit of the indigent, they are not supported by the state, but depend for their maintenance on public and private charity. If, therefore, Assemblyman Henry's bill to provide the City of New York with a hospital for the treatment of pulmonary tuberculosis, at the expense of the State, becomes a law, as it doubtless will, a new departure with regard to this disease will have been taken. The desirability, and, indeed, the need, of special hospitals for consumptives is obvious, for, leaving out of the question the danger such patients are in general hospitals as a source of infection, the fact should be considered that, while they themselves will benefit to an immeasurable degree by the change of treatment, they will also no longer be a burden upon institutions which can ill bear the extra pecuniary stress. The projected undertaking is in the nature of an experiment, the success of which will hinge mainly on the manner of its conduct. It is consequently incumbent upon those intrusted with the control of this institution that they proceed warily and discreetly, that they insist upon the medical staff being selected for their professional ability alone, irrespective of political considerations. Provided that this course is pursued, and if the good results anticipated from the system are justified by experience, it will be safe to predict that money expended in so worthy a cause will be readily forthcoming, and similar establishments will be erected in sufficient numbers to meet the requirements of the situation. The tentative effort of New York City to deal with its dependent consumptives will be watched with interest in all parts of the country.

A BOARD OF EXAMINERS IN MIDWIFERY.

A bill has passed both houses of the legislature of this State, authorizing the creation of a Board of Examiners in Midwifery in this city, composed of the assistant sanitary superintendents of the board of health. As representing the medical profession of the State, we have protested against the enactment of this measure, for the reasons, first, that the practice of midwifery, being a part of the practice of medicine, should be restricted to registered practitioners of medicine; the legalizing of this practice by others will tend to perpetuate a system which we hope in time to succeed in having abolished; and second, if by any train of circumstances it should be considered advisable to legalize this practice by other than registered physicians, we believe any act of legislature with this object in view should apply to the whole State, and not be restricted to one city or county. We believe, if midwives are to be examined and licensed, the work of examining them should be placed in the hands of the State board of medical examiners.

Examine for fish bones in the throat with the finger, since they are not always seen in the throat mirror.

News of the Week.

For a Free Dispensary. — By the will of the late Jacob Justice, who died recently in Philadelphia, his residual estate, amounting to about $60,000, is devised for the establishment of a non-sectarian dispensary for the treatment of the poor and the distressed, at Mt. Pleasant, Westmoreland County, Pa.

Philadelphia Pediatric Society.—At a stated meeting held April 10th, Dr. Alfred Hand, Jr., read a paper on "The Pathology of Congenital Heart Disease"; Dr. J. Dutton Steele one on "The Pathology of Acquired Heart Disease in Children"; Dr. F. A. Packard one on "The Symptomatology of Heart Disease in Children"; Dr. J. P. Crozer Griffith one on "The Diagnosis of Heart Disease in Children"; Dr. A. V. Meigs one on "The Prognosis of Heart Disease in Children"; and Dr. H. A. Hare one on "The Treatment of Heart Disease in Children."

Philadelphia County Medical Society.—At a stated meeting held April 11th, Dr. A. A. Eshner read for Dr. David Riesman the report of a case of elephantiasis of the leg, and exhibited the patient. The disorder was unilateral, involving more especially the leg, but also to a less degree the thigh. No known etiological factor could be elicited, nor did examination of the blood disclose the presence of filaria sanguinis hominis. Dr. Herman D. Allyn read a communication entitled "The Symptomatology and Diagnosis of Empyema, with a Report of Illustrative Cases," Dr. Joseph MacFarland one entitled "The Etiology and Pathology of Empyema," and Dr. Edward Martin one on "The Surgical Treatment of Empyema."

College of Physicians of Philadelphia. — At a stated meeting of the section on general medicine held April 9th, Dr. F. A. Packard presented intestinal casts from cases of mucous enteritis, and concretions of fat from a case of possible pancreatic disease. Dr. William G. Spiller presented a case of progressive bulbar paralysis and one of progressive spinal muscular atrophy, pointing out that in both the lesions involved the gray matter, in the one instance of the medulla oblongata and in the other of the anterior horns of the spinal cord. Dr. Spiller exhibited a specimen of spinal cord presenting a hard, flattened neoplasm in the cervical region, and reported a case of compression of the upper part of the cervical cord with unusual symptoms. Dr. C. W. Burr reported a case of Pott's disease presenting varying types of anæsthesia. Dr. M. Howard Fussell reported a case of myxœdema that had not been benefited by thyroid treatment.

Pathological Society of Philadelphia.—At a stated meeting held April 12th, Drs. S. Solis-Cohen and T. S. Kirkbride, Jr., presented communications entitled "Tumor of the Mediastinum and Bronchial Glands and of the Right Lung," "Metastasis in the Liver," "Rupture with Fatal Hemorrhage." During life the growth was thought to be a carcinoma, but on histological examination it was found to be a sarcoma. The liver weighed fifteen pounds, and death was due to spontaneous rupture of this organ. Dr. H. F. Harris read a paper entitled "Remarks upon the Pathological Alterations in Bubonic Plague," and he exhibited microscopic preparations of the diseased tissues. Dr. F. P. Henry exhibited a hydatid cyst of the liver. Dr. J. Walsh made a report of a pathogenic sarcina. Drs. J. M. Anders and Joseph McFarland presented a specimen of carcinoma of the stomach with perforation. Dr. Joseph McFarland presented a specimen of carcinoma of the stomach. Dr. S. Solis-Cohen presented a specimen of valvular disease with hypertrophy of the heart and healed hemorrhagic infarct in the spleen.

The American Dermatological Association will hold its twenty-fourth annual meeting at the Hotel Gordon, Washington, on May 1st–3d, in connection with the fifth triennial session of the Congress of American Physicians and Surgeons. The president is Dr. Henry Weightman Stelwagon, of Philadelphia.

The Pennsylvania Society for the Prevention of Tuberculosis, at its eighth annual meeting held at Philadelphia on April 11th, elected the following officers: *President*, Dr. Guy Hinsdale; *Vice-Presidents*, Drs. H. S. Anders, J. Solis-Cohen, and S. A. Knopf, and Messrs. William Moss, Moses Veale, and Walcott Williams, Miss E. W. Redfield, and Mrs. Helen C. Jenks.

State Hospital for Consumptives. — Governor Roosevelt has appointed the following trustees of the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis, which is to be established in the Adirondacks: Howard Townsend, of Manhattan, for the term of five years; Dr. John H. Pryor, of Buffalo, for four years; Dr. Willis G. Macdonald, of Albany, for three years; Walter Jennings, of Manhattan, for two years; Frank E. Kendall, of Saranac Lake, for one year. A preliminary appropriation of $50,000 has been made to establish the hospital, which will cost in the neighborhood of $200,000. The hospital is to be established in the Adirondacks, upon a site to be approved by the State board of health and the State forest preserve board. The trustees are to purchase a thousand acres as a site for the hospital, and the State forest and preserve board is to set apart a like amount of State lands for such purposes.

The Tenement-House Commission, recently appointed by Governor Roosevelt, is constituted as follows: Messrs. Raymond T. Almirall, of Brooklyn; Hugh Bonner, of Manhattan; Paul D. Cravath, of Manhattan; Robert W. De Forest, of Manhattan; William A. Douglas, of Buffalo; Otto M. Eidlitz, of Manhattan; F. Norton Goddard, of Manhattan; William Lansing, of Buffalo; William J. O'Brien, of Manhattan; James B. Reynolds, of Manhattan; I. N. Phelps Stokes, of Manhattan; Myles Tierney, of Manhattan; Alfred T. White, of Brooklyn; and Dr. George B. Fowler, of Manhattan. The duty of the commission is to make careful examination into the tenement houses in New York and Buffalo; their condition as to the construction, healthfulness, safety, rentals, and the effect of tenement-house life on the health, education, savings, and morals of those who live in tenement houses, and all other phases of the so-called tenement-house question in these cities that can affect the public welfare. An appropriation of $10,000 is made for the expenses of the commission, which may subpœna and compel the attendance of witnesses, employ counsel, assistants, and experts, and make such recommendations to the next legislature as it deems wise, to enable the best and highest possible condition for tenement-house life in New York and Buffalo to be attained.

Incorporation of the New York State Medical Association.—The governor has signed Dr. Henry's bill incorporating the New York State Medical Association for the purpose of the cultivation and advancement of the science of medicine, the promotion of public health, and the establishment of a death benefit fund for the dependents of its members.

The Marine-Hospital Service.—A board of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, May 23, 1900, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital service. Candidates must be between twenty-one and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: (1) Physical; (2) written; (3) oral; (4) clinical. In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address Supervising Surgeon-General, United States Marine-Hospital service, Washington, D. C.

The Texas State Medical Association.—The thirty-second annual meeting of this society will be held at Waco on April 24th, 25th, 26th, and 27th, under the presidency of Dr. A. B. Gardner, of Bellville.

A New Hospital, constructed and equipped on modern lines, was dedicated at Phœnixville, Pa., on April 14th. The building is one hundred and two feet deep by one hundred and fifteen feet long, five stories high, contains sixty-seven rooms, and cost about $50,000.

The Drug Clerks' Bill.—Governor Roosevelt has signed the bill providing for shorter hours for the drug clerks in the city of New York, and for the inspection of drug stores by the local board of health. Under its provisions drug clerks are prohibited from sleeping in the stores or in apartments connecting with the stores.

The International Medical Congress.—The three general sessions of the Paris Congress will be held in the large amphitheatre of the Sorbonne. As this hall accommodates only three thousand persons it is feared that many of the members will be excluded from the opening session. At the two subsequent sessions the difficulty will probably be to secure an attendance large enough to compliment the orators.

Mothers and Babies' Hospital, New York.—Mrs. Howard Gould has equipped an operating-theatre for this hospital which will seat an audience of one hundred and twenty students. This will be a very desirable addition to the teaching facilities of this growing institution, as obstetric clinics are now being held there in connection with four of the medical colleges of this city.

The Cartwright Lectures.—The first of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, Columbia University, was delivered at the Academy of Medicine on April 18th. The subsequent lectures of the course will be on April 24th and 26th. The subject is "The Discovery of the Nerves and of their Function," and the lecturer is Prof. John G. Curtis, M.D., of Columbia University.

A Relief Ship for India.—A joint resolution of Congress adopted in 1897 authorized the Secretary of the Navy to charter two ships, one on the Atlantic and one on the Pacific coast, to carry relief supplies to India. One ship was sent from San Francisco, but it was decided to sell the supplies intended to go from New York and transmit the money obtained by that means. Recently application was made to the government to charter a ship from New York to take a large quantity of supplies awaiting shipment from this port. The treasury officials have decided that the authorization of 1897 has not lapsed, the famine still existing, so an order has been issued to charter the vessel.

Dr. Francis M. Banta, who was dismissed from his position as surgeon in the fire department in September, 1898, has been reinstated by the supreme court. The dismissal was made by the fire commissioner without cause or charges, after Dr. Banta had served more than three years.

The Fatality of Influenza still continues, forty-six deaths from this cause being reported to the Philadelphia bureau of health for the week ending April 14th. Diseases of the respiratory tract were responsible for a large proportion of the whole number of deaths. Thus, 134 were due to pneumonia, 9 to congestion of the lungs, 53 to pulmonary tuberculosis, 15 to bronchitis. In addition 47 deaths were due to disease of the heart, 28 to convulsions, 36 to nephritis, 24 to apoplexy, 22 to measles, 21 to old age.

The Pretoria Red Cross.—The chairman of the American committee to aid Red Cross work within the Boer lines in South Africa has received a letter from a member of the committee, who is in the Transvaal, in which it is stated that Pretoria Red Cross is in great need of medicines, instruments, wagons, etc., and the committee is asked to send money for supplying those necessities directly to the Red Cross authorities in Pretoria. The treasurer of the committee is Mr. T. G. Bergen, 55 Liberty Street, New York.

The Spitting Nuisance.—An effort is being made by the sanitary superintendent of the board of health in Brooklyn to enforce the law against spitting on the floor of elevated and trolley cars in that borough. There are notices in the cars there, as there are here, but hitherto the law has been ignored there, as it is still in Manhattan. The penalty for spitting on the floor of a public conveyance is a fine of from $1 to $250. In Paris a law has recently been passed forbidding spitting in public places, and our London contemporaries are lamenting that no such rule exists there. It is, however, better to have no law at all than to have it so persistently defied as it is in New York.

The New York State Board of Charities, at its annual meeting on April 12th, re-elected Mr. William Rhinelander Stewart, of New York City, as its president for the eighth consecutive term, and Dr. Enoch V. Stoddard, of Rochester, as vice-president for the sixth consecutive term. The incorporation of the following institutions was approved by the board: The Dobbs Ferry Hospital Association; the Maronite Benevolent Society of New York City; Guild for Crippled Children of the Poor of New York City; House of Calvary, New York City; Ladies' Hebrew Benevolent Association of Greenpoint; Hebrew Ladies' Relief Association of Rochester, and the Corning Hospital. The board also approved plans for a hospital for both the Monroe and Onondaga county almshouses and plans for small buildings at the Craig Colony and Western House of Refuge, as well as plans for building improvements by the Brooklyn Charities' Department. Dispensary licenses were granted to the following institutions: The Vanderbilt Clinic, Sixtieth Street and Amsterdam Avenue, New York City, and Dispensary of Loomis Sanitarium for Consumptives, City Branch, 104 West Forty-ninth Street, New York City.

Yellow-Fever Ships in Port.—Deaths from yellow fever occurred on several steamships arriving here recently from Brazilian ports. Quarantine against vessels from Cuba has already been established in the southern coast cities.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 14, 1900. April 11th.—Passed Assistant Surgeon F. W. Olcott ordered to duty at the naval recruiting rendezvous, Philadelphia, Pa.

The Hospital Saturday and Sunday Collection.—The collections of the Hospital Saturday and Sunday Association for this year amount to more than $74,000, nearly $4,000 above last year. The Woman's Auxiliary collected over $9,000. The books are now closed, and the money collected will be distributed among the hospitals soon.

Hospitals for Animals in Central Park.—A hospital for sick horned animals is being constructed between the deer paddock and the east bridle path in Central Park. The building will contain four stalls. Another hospital for invalid lions, tigers, and other caged animals is to be put up in another part of the menagerie.

Damages for a Dislocated Kidney.—A man and his wife have obtained a verdict of $10,000 against the Pennsylvania Railroad Company in the New Jersey supreme court, for injuries received by the woman while on a train. A jolt occasioned by attaching a new car to the train threw the woman down, and her physician testified at the trial that the accident was the cause of a movable kidney from which she suffered. The court awarded the woman $8,000, and her husband $2,000 for the loss of her companionship.

The Plague.—In Sydney, N. S. W., one hundred and eleven cases of bubonic plague and thirty-eight deaths had occurred up to April 13th. A death from the disease has been reported from Fremantle, a town of Western Australia, at the mouth of the Swan River, twelve miles south of Perth.—Several cases of plague have occurred at Cawnpur, in the Northwest Provinces, India, not far from Lucknow. The natives opposed the sanitary measures instituted, and a riot took place. The segregation camp was burned, and ten persons were killed. The rioters killed five constables and threw their bodies into the burning camp. It was necessary to call out the garrison and volunteers before order was restored.

The State Orthopedic Hospital.—Governor Roosevelt has signed the bill establishing the New York State Hospital for the care of cripples and deformed children in or near New York City, and appropriating $15,000 therefor. The governor has also appointed a board of managers for the institution, as follows: To serve for six years, Dr. Newton M. Shaffer; four years, Right Rev. Henry C. Potter and Mr. J. Hampden Robb; two years, Messrs. J. Adriance Bush and George Blagden, Jr. Dr. Shaffer is also appointed surgeon in chief of the hospital.

A Death from Hydrophobia occurred recently at St. Vincent's Hospital. The man was bitten by a St. Bernard dog on March 9th, and appeared to be well until April 7th, when he began to suffer from depression, and soon symptoms of rabies appeared and he rapidly succumbed.

Obituary Notes.—DR. GEORGE H. CONKLIN, the oldest physician in Suffolk County, died April 12th at Babylon, N. Y., at the age of eighty-nine years.

DR. EDWARD MULHERON, of Binghamton, N. Y., died at his home in that city April 6th, aged fifty-three years. He was a graduate of the medical department of the University of Buffalo in 1872.

DR. JOHN STIRLING BIRD, of Hyde Park, Dutchess Connty, died April 3d of pneumonia. He was born in Winchester, Conn., August 29, 1836. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1863, and opened an office in Hyde Park for the practice of his profession in 1865. He was a member of the Dutchess County Medical Society.

DR. THOMAS R. HOSSIE, of Gouverneur, N. Y., died on April 14th, at the age of forty-one years. He was a graduate of Queen's University, Kingston, Ontario, in 1878. He was a prominent Mason.

DR. FRANK D. KIMBALL, twenty-four years old, for two years house surgeon of the City Hospital on Blackwell's Island, died April 12th at the New York Eye and Ear Infirmary of suppurative meningitis following influenzal mastoid disease. Dr. Kimball was a graduate in arts of Dartmouth College and in medicine of the New York University Medical College in the class of 1898.

DR. THOMAS FRANCIS ROCHE, for fourteen years resident physician at Deer Island, Boston harbor, died at his home in East Boston, April 8th, at the age of thirty-seven years. He was graduated from the Bellevue Hospital Medical College, New York, in 1883.

DR. CHARLES C. EASTMAN, assistant manager of the Binghamton State Hospital, died April 12th. He was a graduate of the Geneva Medical College in 1866, and had been connected with the hospital since it was opened in 1881.

DR. ROBERT F. CUNNION, of Brooklyn, died suddenly on April 7th, at the age of thirty years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1892.

REV. ALFRED YOUNG, a Roman Catholic priest, and one of the founders of the Paulist community in this city, died on April 4th. He was born in Bristol, England, on January 21, 1831, and when seven years old he was brought to this country by his parents. He was graduated from Princeton University in 1848 and entered the medical department of the University of New York. From there he was graduated in 1852. He then began practice, but a year later abandoned it to study for the priesthood.

DR. WILLIAM HENRY STUART died at his home in Norwich, N. Y., on April 8th, at the age of fifty-nine years. He was a graduate of Albany Medical College in 1861, and served as surgeon of New York volunteers during the civil war. At the close of the war he began practice in Ellenville, and in 1871 removed to Norwich.

DR. FRANCES C. HATCHETTE died at Philadelphia on April 13th, at the age of forty years. She studied medicine in the Harvard Annex and did post-gràduate work in Philadelphia.

SIR WILLIAM OVEREND PRIESTLY, member of the House of Commons for Edinburgh and St. Andrew's Universities, died in London on April 11th. He was born in 1829, and was a grand-nephew of Joseph Priestly, the celebrated chemist. He was M.R.C.S. in 1852, M.D. Edin. in 1853, and F.R.C.P. Edin. in 1858.

DR. ISAAC C. HARING, of West Nyack, N. Y., died April 16th. He was a graduate of the Albany Medical College in the class of 1850, and had practised in Rockland County for half a century.

Progress of Medical Science.

New York Medical Journal, April 14, 1900.

Remarks on Perineorrhaphy, Chiefly in Reference to the Mechanics of Deep Sutures.—J. M. Mabbott maintains that in order to perform this operation properly the suture should be introduced so as to be elliptical with its long axis transverse. If we use sutures passing beneath the deep angle of the wound, we must carry them so far out to the sides that they will include enough tissue for each suture to be drawn to a circular form without crowding the lacerated surfaces out of their natural relations to each other and surrounding parts. The more deeply we carry the suture toward the sides of the pelvis the more traction we shall secure in the right direction—toward the median line. And until such a suture approaches a circular shape, it will not only be drawing the sides together, thus holding the lacerated surfaces in forcible coaptation, but it will at the same time have some tendency to bulge the cutaneous vaginal and rectal surfaces away from each other, thus giving a thick, firm perineal body.

Ankylostomiasis in Puerto Rico.—B. K. Ashford reports upon twenty cases of the severe form of anæmia seen in the island, giving in detail the typical family history, the previous history of the patient, subjective and objective symptoms. Observations show that these conditions are due to an intestinal parasite known as the ankylostoma duodenale. Thymol in large internal dose seems to be an efficient anthelmintic. Examination of the blood showed a severe anæmia, falling as low as that of Addison's disease in count of red cells, a low hæmoglobin average, and a very low color index; an occasional eosinophilia, no leucocytosis common to the disease itself, frequent presence of normoblasts, and in some instances megaloblasts but never a majority of the latter, and commonly poikilocytosis. Blood foods are utterly unreliable without the removal of the cause, viz., the ankylostoma.

A Few Experiments in Transfusion of Complete Blood.—From experiments of transferring blood from a chicken to a rabbit, A. D. Hard found that the temperature of the latter was increased. The same result followed transfer from sparrow to guinea-pig, but from land turtle to guinea-pig the temperature of the latter was diminished. In all three instances it was some days before the normal temperature was restored. Results are also given of transferring blood from a goat to the author's own veins, which produced an increase in red and white blood cells and in hæmoglobin percentage. Subjectively the author noticed a "peculiar mental acuity and facility of thought processes accompanied by undue exuberance of spirits of an optimistic nature."

Books are Injurious to the Eyes.—F. G. Murphy discusses what may be called the mechanics of reading with reference to the angle of vision, the direction from which the light falls on the printed page, and the differences in the mechanical problems presented by books and newspapers, the wide page of the book causing greater strain on the eyes than the narrow column of the newspaper.

A Report of Gunshot Cases in the Spanish-American War, and Deductions Therefrom.—By W. C. Borden.

Primary Diffuse Small-Celled Sarcoma of the Parietal Pericardium.—By J. C. Williams.

Boston Medical and Surgical Journal, April 12, 1900.

Folie à Deux.—Arthur C. Jelly writes of communicated insanity, cases of which, he says, are very rare. Heredity is the most important etiological factor. Women are affected more than men. The young and the aged are most liable to the infection. Two groups show clearly the effects of contagion: (1) Where A, who is insane, infects with the same disorder of mind B, who was previously sane; (2) where A, who is insane, infects with the same disorder of mind B, who was already insane. In other cases it is doubtful how much of the disturbance is due to actual contagion, for example: (1) Where A and B, living together, suffer simultaneously from the same form of insanity due to the same causes; (2) where B becomes insane from association with A, not necessarily because he accepts A's morbid ideas, but in consequence of the shock produced by the news, or of the pain felt on witnessing the attack, or of the continued strain due to nursing the patient. The author gives illustrative cases. Separation is the best treatment.

The Use of the Angiotribe.—J. Riddle Goffe claims that with the use of this instrument the blood-vessels are better controlled than with forceps, and more space is gained to work in. There is no protrusion of forceps handles, no removal of forceps with perhaps attendant hemorrhage. Convalescence is smooth and comfortable, and there is less pain than by the use of forceps or ligatures. The angiotribe is superior to forceps in that it is more easily and quickly applied, and is attended by less discharge during convalescence, whether the ligature used is catgut or silk. In the author's opinion the angiotribe has a field of application in dealing with hemorrhoids, and he believes that it will be proved to be superior to the ordinary clamp and cautery.

A Case of Intestinal Obstruction from a Hair-Ball.—G. W. W. Brewster reports a fatal case of a girl from whom a hair-ball three and one-half inches long and four and one-half inches in circumference was removed from the small intestine. She had had the habit of chewing her curls.

Hair-Eating Children and Convulsions.—Frederick Lyon was called to see a child in convulsions, and learning that it had a habit of swallowing hair or fibre from blankets, carpets, shirt, etc., gave it calomel. A ball of hair was passed and the convulsions ceased.

The Problem of Boston's Insane.—By Philip Coombs Knapp.

The Work of the Trustees of the Boston Insane Hospital.—By Henry C. Baldwin.

Philadelphia Medical Journal, April 14, 1900.

The Control of Hemorrhage in Penetrating Wounds of the Chest.—Robert G. LeConte formulates the following rules of action in case of penetrating wounds of the thorax: When the wound of the lung is giving only slight hemorrhage, close the external wound with gauze and watch for the physical signs of bleeding. When the hemorrhage is more marked, open the chest, insert a small drainage-tube, and regulate the admission of air according to the difficulty of respiration in the patient. When the hemorrhage is large and its symptoms are alarming, open the chest and insert a large drainage-tube, so as to form a rapid and complete pneumothorax, and at the same time, when necessary, inject salt solution into a vein. When this does not control the hemorrhage, resect one or more ribs, and deal radically with the bleeding. In severe hemorrhage from a lung, the first object of treatment should be to get pressure on that lung. By opening the chest, air will do this as well as blood in the pleura; it will do it instantly instead of waiting until a sufficient amount of blood has been poured out; it will save to the patient the amount of blood necessary to exert this mechanical pressure; it will permit the vessels to close by clots; and the remote benefits are that it eliminates the dangers of a pyothorax or of universal adhesions of the pleura.

A Peculiar Manifestation of Uræmia.—Frederick Krauss reports the case of a woman who had several attacks of convulsions followed by coma. There was conjugate deviation of both eyes to the left, and the twitchings were on this side; the right side seemed paralyzed. The woman was a stranger to him, but suspecting uræmia he catheterized her and examined the urine. It was apparently normal, containing no albumin and having no sediment. The woman died soon after the writer saw her, and at the autopsy the kidneys were found to be the seat of nephritis. The brain was slightly œdematous and congested, as it frequently is in uræmia, but there were no gross lesions and no fracture of the skull. The only lesions that could possibly have caused the symptoms observed and death were those of the kidneys.

A Case of Death from Psychic Insult.—E. Pagenstecher reports the case of a manufacturer, fifty-one years of age, in apparent mental and physical health, who cut his finger slightly when sharpening a pencil and then accidentally soiled the wound with ink. He was greatly alarmed, fearing blood-poisoning, and begged his physicians to amputate the arm. He complained of pains in the arm, and fainted. The following day he was delirious, and he died thirty-two hours after the receipt of the injury. The cause of death was difficult to determine, but as there was marked concentric hypertrophy of the left ventricle it was thought possible that cardiac insufficiency may have been the immediate cause of the fatal ending.

Selections from the Lane Lectures. By T. Clifford Allbutt.

A Case of Malarial Fever.—By Albert Woldert.

Abdominal Pregnancy.—By Center.

Medical Press and Circular, March 28, 1900.

Infantile Insanity.—Walter Bernard thinks the family physician, holding as he does the key to the family pedigree and ancestral history, and by reason of his opportunities of observation before mental action and mentation are evolved, is in a position to control inherited conditions. Reformatory influences must commence at home. The earliest possible diagnosis is of vital importance. Peculiarities and disordered states of the faculties can at this period be blotted out.

Cases of Skin Disease.—Alfred Eddowes presented a girl with lupus of the face simulating verruca necrogenica requiring surgical treatment; also a case of lupus erythematosus of the scalp of twelve years' duration with horny plugging of the hair follicles, showing beginning butterfly-forms on the face. The third case was that of a girl recovering from leucoderma. The writer believes the disease curable by drugs, but refrains from mentioning what line of treatment he pursues.

Acute Inflammation of a Subperitoneal Fibroid.—Dr. Walter relates the case of a patient four months pregnant, who five days before admission had been seized with pain in the abdomen. A hard tumor was felt on the left side. An exploratory incision revealed a subperitoneal fibroid the size of an orange attached to the left and front part of the fundus. Rapid recovery took place. There had been no miscarriage up to the time of the report.

Some Cases of Gynæcological Surgery.—By E. Stanmore Bishop.

Surgery of the Stomach.—By A. Mayo Robson.

Journal of the American Medical Ass'n, April 14, 1900.

Some of the Aspects of Renal Inadequacy from a Neuropathic Standpoint.—H. A. Tomlinson reports two cases. He considers the following conclusions warranted by our study of the clinical aspects of renal inadequacy during the past five years, supplemented by the uranalysis and post-mortem verification of the deductions made: Renal inadequacy as a temporary condition, not necessarily dependent upon histological changes in the kidney structure, is quite common, especially during adult life and after. There is definite clinical evidence that in some people renal inadequacy is congenital and dependent on limited potentiality—usually nervous. The amount of the total solids in the urine, or the presence or absence of albumin or casts, furnishes no direct evidence of impending uræmia, but the relative proportion of the solid constituents to each other does furnish such evidence.

Use of Atropine Sulphate as a Means of Diagnosis in Certain Persistent Headaches.—Otto Landman says that the headaches which are most frequently produced by ocular defects are situated, as to their frequency, in the following regions: supraciliary, occipital, occipito-frontal, vertex, and temporal; and his conclusion is that when a persistent headache situated in any of these localities disappears on the instillation of atropine, the case is probably due to eye strain, and can be remedied by proper glasses. To obtain the result, the atropine must be pushed to the complete suspension of accommodation. The directions for use are as follows: A solution of gr. ¼ of sulphate of atropine to ʒ ii. of water, three drops in each eye, three times a day, until ten instillations have been made.

Dosage in Chloroform Anæsthesia.—A. S. v. Mansfelde speaks of the responsibility of anæsthetizers and the partisan spirit of controversy as to the relative value and safety of anæsthetics. The writer says that to obtain the full value of an anæsthetic it is quite necessary that the ingredients be in the form of a vapor, to be inhaled by the patient in exactly measured quantities in a given time, and diluted to a known strength with air. He describes the apparatus of Professor Geppert, which claims to meet these requirements, and which this author believes will furnish the ideal solution of the problem for the future.

Shoulder-Humero-Scapula Articulation.—In a paper with this title Thomas H. Manley concludes a review of some complications and sequelæ attending or following reducible or irreducible dislocations, together with various modern operative measures now employed for their treatment.

Symposium on Serum Therapy.—Papers read at a meeting of the New York County Medical Association, reported in the Medical Record of April 7, 1900.

Report of a Successful Case of Excision of the Cæcum, with End-to-End Anastomosis.—By Frederick Holme Wiggin.

Medical News, April 14, 1900.

Ligation of the First Portion of the Right Subclavian for Aneurism of the Third Portion.—In this case, reported by A. E. Halstead, the aneurism involved the entire third portion of the subclavian and encroached slightly upon the second portion, so that the only rational method of treatment was ligation of the first part. The ligatures employed were of formaldehyde catgut. The author says that probably the most important factor in securing favorable results in these cases is the preservation of an aseptic condition of the wound. As regards the results thus far obtained in the ligation of the first portion of the right subclavian, the writer believes this case to be the second on record in which the patient survived the operation.

Two Cases of Recurrent Tubal Pregnancy.—Philander A. Harris reports these two cases, in each of which abdominal section was performed twice, resulting in good recoveries. The writer says that cases of ectopic gestation recurring in the same individual are, no doubt, rare. He refers to four other cases, three of which are reported by Kelly.

Recent Advances in the Treatment of Insomnia.—By Reynold Webb Wilcox.

Purulent Meningitis: Report of Six Cases.—By L. Napoleon Boston.

The Legislation Needed in Regard to Apparent Death.—By Henry J. Garrigues.

British Medical Journal, April 7, 1900.

The Gelatinous Form of Sodium Biurate and its Bearing on the Treatment of Gout.—Arthur P. Luff has studied the action of various drugs upon the sodium biurate in the blood, and formulates the following conclusions: (1) The sodium salts accelerate the conversion of the gelatinous biurate into the less soluble crystalline variety; (2) potassium salts delay the conversion of the gelatinous biurate into the crystalline form, and when the conversion is once started it is slowed by the presence of these salts; (3) lithium salts do not delay the initial conversion of the gelatinous biurate, but when the conversion is once started it is slowed by the presence of these salts, and especially by the carbonate; (4) piperazin does not delay the initial conversion of the gelatinous biurate, and but slightly slows the conversion when once started; and (5) lysidin delays the conversion of the gelatinous biurate into the crystalline form, but when the conversion is once started it has practically no effect in slowing it. From the results of the experiments it appears that in the treatment of gout the potassium salts are the most useful, the lithium salts rank next, and piperazin and lysidin are not nearly so useful. These results, the writer says, are in accord with his clinical experience.

The Action of Various Drugs and Diets on the Excretion of Nitrogen in Gout.—William Bain records the results of a number of dietetic experiments in a gouty subject. The diets were as follows: Fixed Diet—Cacao 1 pint, tea 2 pints, milk 1 pint, tea cake 2 oz., bread 11 oz., butter 1 oz.; dinner, 1 lb. 6 oz., including 4 oz. of meat and 1 apple. Vegetable Diet—This consisted to a large extent of peas and beans. Milk 1½ pints, oatmeal porridge ½ pint, pea soup ½ pint, peas porridge ½ pints, bread 11 oz., butter 1 oz., peas, beans, and other vegetables 1 lb. 8 oz. Animal Diet—Milk 1½ pints, lemonade 1 pint, meat 10 oz., bread 10 oz., butter 1 oz., potatoes 4 oz., and 1 apple. In addition to being dieted, the patient took the same amount of exercise each day. The excretion of uric acid, phosphorus pentoxide, and alloxur bases was greatest while the man was on the vegetable diet, and least when he was on the fixed diet. The administration of guaiac caused a marked and of colchicum a slight increase in uric-acid excretion.

A Note on the Telephone Probe.—J. C. Ogilvie Will says he made use of a telephone probe for the location of a bullet in a patient at the Aberdeen Royal Infirmary thirteen years ago. The employment of the instrument was suggested by Mr. McKenzie Davidson.

When is Cancer Cured?—George Elder reports cases of recurrence of cancer *in loco* or in a distant part five and eighteen years after removal. He also reports the case of a woman dying of pulmonary disease in 1899, who had had an atrophic cancer of the breast since 1880.

Puerperal Eclampsia in a Patient Aged Fifteen Years; Recovery.—By D. R. G. Corrigan.

Incomplete Inversion of the Uterus.—By J. H. Wilson.

An Operation for Complete Atresia Vaginæ.—By J. M. Cotterill.

Practical Observation on Cancer of the Breast.—By Sir William Banks.

The Typhoid Bacillus and Typhoid Fever.—By P. Horton-Smith.

Some Cirrhoses of the Liver.—By W. B. Cheadle.

The Lancet, April 7, 1900.

Practical Observations on Cancer of the Breast.—In the third Lettsomian lecture Sir William Banks reviews the various stages of development of the parasitic and infective views of cancer. He believes that as yet there is no clear and indisputable proof of its infectivity, and that any strong statements to that effect, or to the effect that surgeons infect wounds by disseminating cancer products through them by operation, are not justified. On the other hand the results of recent study render it impossible to dispose of this phase of the cancer question lightly. The present is not the time for positive assertion in this regard. Rather should we patiently experiment and carefully collate facts for future judgment.

Some Cirrhoses of the Liver.—In the second Lumleian lecture W. B. Cheadle considers several of the associated lesions such as degeneration of heart muscle, concurrent interstitial fibrosis of other organs, and the liability to erysipelas and tuberculosis. He believes that the lines of distinction between the various forms of cirrhosis are at present too rigidly drawn, and that, as at present laid down, they hold good only with regard to typical examples. Favorable condition are, first, the enlargement of the liver; second, good nutrition, and third, youth. Even some of the cases directly referable to alcohol and syphilis do surprisingly well.

A Parasitic Crustacean as a Foreign Body on the Cornea.—R. D. Batten reports the case of a fishmonger who probably rubbed his eye after handling fish. The parasite was of the variety known as "caligus curtus."

The Uses of Oxygen Inhalation.—P. G. Lodge gives his personal experience with this remedy in various pulmonary affections. He believes in using it intermittently so as not to set up a dangerously protracted state of apnœa.

A By-Result of Vaccination.—W. G. Mortimer vaccinated a man who had been greatly troubled with warts around the nails and on the chin. Four days after inoculation the warts began to diminish, and in a short time they had entirely disappeared.

Concurrent Pneumonia, Diphtheria, and Typhoid Fever.—This unusual combination of maladies occurred in a soldier under the care of D. Harris; recovery took place.

Typhoid Fever of Prolonged Duration.—H. E. Belcher narrates the history of a case in which the temperature did not reach the normal until the one hundred and fifth day of the disease.

Remarks on the Physical Signs of Pulmonary Disease.—By P. H. Pye-Smith.

The Surgical Treatment of Dilatation of the Stomach.—By L. A. Bidwell.

Münchener medicinische Wochenschrift, March 27, 1900.

Epigastric Hernia.—Eichel says that epigastric hernia occurs between the xiphoid process and umbilicus, mostly in the middle line but occasionally a little to the right or left. It produces a tumor of varying size, usually as large as a hazelnut. Its causation, diagnosis, and treatment are discussed at length.

Nervous Disturbances of the Heart in their Relation to Military Service.—J. Bauer concludes that all young men with functional cardiac disturbances are by no means unfit for military service; on the contrary, for some the gradual strengthening of the heart muscle acts as a direct cure.

Tuberculosis.—Henkel advocates puncture of the lung in order to find the tubercle bacilli in the incipient cases. He maintains that the earliest physical signs are auscultatory, and are heard over the supra- and infra-spinatus regions.

Operation upon the Heart after Pistol Wounds.—Carl Stern describes a case in which he followed the typical operation of Rother with a fatal result. The diagnosis and indications for interfernce are also discussed.

Pseudomucin in Ovarian Cysts.—By Zängerle.

Agglutinin.—By Hahn and Trommsdorff.

Addison's Disease.—By L. Huysmans.

Berliner klinische Wochenschrift, March 26, 1900.

Diagnostic and Therapeutic Significance of Tubercle Bacilli and Other Bacteria in the Sputa.—L. Brieger corroborates the statements of Fraenkel as to the diagnostic value of tuberculin when properly employed, and calls attention to the necessity of determining at the earliest possible moment the existence (if present) of mixed infection. This is shown by the occurrence of fever (for pure tuberculosis is essentially an afebrile disease) and by the presence of various micro-organisms in the expectoration. This mixed infection frequently appears as a lobular or even lobar pneumonia, producing the presence in the sputa of staphylococci, streptococci, and pneumococci. The later stage of pulmonary tuberculosis therefore becomes a chronic sepsis. The condition is still more rapidly accelerated by the occurrence of the influenza bacillus in the lungs. Various other organisms have been found, as for instance the bacillus pyocyaneus. Much of the evil from this mixed infection can be averted or lessened if vigorous measures are instituted early in the course of the disease.

Etiology and Operative Radical Treatment of Genuine Ozæna.—Nöbel and Löhnberg conclude a series of articles by advancing the following propositions: (1) By far the greater number of cases of nasal purulent discharge appearing as ozæna are referable to affections of the sphenoid and ethmoid sinuses. (2) Fetor, atrophy, and crust formation as expressions of pus in the nose can be produced by a number of causes, but as a rule are referable to purulent foci in sphenoid and ethmoid. (3) A rational treatment of ozæna in any given case can be expected only upon the discovery of its primary cause. (4) Since these causes are mostly sphenoidal or ethmoidal in origin, the therapy of ozæna must be a surgical one or it will be without result.

The Development of the Theory of Inflammation in the Nineteenth Century.—Ponfick discusses in this final paper the causes of inflammation, especially in the light of the establishment of the science of bacteriology. He defines inflammation as "a disturbance which, produced by an overthrow of tissue balance, associated with a change in the vessel walls, consists in an exudation of fluid and solid blood elements, and is regularly accompanied by formative and frequently by degenerative changes in the cells of the basement substance."

The Diagnostic and Prognostic Significance of the Diazo Reaction in Phthisical Patients.—Michealis finds that a positive reaction to this test in pulmonary tuberculosis signifies a bad prognosis. Out of 167 cases, 56 gave a negative and 111 a positive reaction. Of the former group, 5 patients were cured, 44 improved, 5 unchanged, and 3 died. Of the latter group none were cured, 15 improved, 13 not improved, and 80 died.

Local Anæsthesia and Narcosis.—C. L. Schleich makes a plea for the more general employment of local anæsthesia, showing that many operations thought to require general anæsthesia can be done under local methods as at present elaborated.

La Riforma Medica, March 19, 20, and 21, 1900.

The Disinfection of the Nasal Cavity with Certain Essences and Essential Oils.—A. de Simoni initiated a series of experiments upon animals in order to ascertain what substances would destroy certain germs in the nasal cavity, and at the same time prove innocuous to the mucous membrane. He reaches the conclusion that pure essences are so decidedly curative in grave lesions of the mucosa as to justify their more extensive use in the field of rhinology. Disinfection by means of volatile essences is the most thorough, and the most practicable. They are less toxic than dilute solutions of bichloride, carbolic acid, etc., and at the same time they stimulate activity of the mucosa and accelerate the healing of the epithelial cells.

Congestion of the Liver from Mercury Poisoning.—Angelo Lisanti writes of the effect upon the liver of mercury in men who use it in their work, as well as in syphilitics who have long taken it therapeutically. In a large number of cases he has found it sensitive to pressure and painful, with smooth surface and increased in size. Rapid modifications in its size occur, and coincide with crises of polyuria and albuminuria. Subjectively there are sensations of fulness and tension in the epigastrium and right hypochondrium, with pain radiating to the right shoulder, and increased by respiration or movement of the body. Suspension of mercurial treatment will cause a cessation of the liver congestion in two or three weeks.

Revue de Médecine, March 10, 1900.

Nervous Hyperthermia in Women.—G. Leven says that out of thirteen cases of so-called nervous fever, which he thinks it would be more exact to call hyperthermia, two patients menstruated normally. In the other cases there was some abnormality of menstruation; in two the fever appeared when menstruation was bruskly interrupted, and in two others the temperature fell when the flow began. The author concludes that there is a relation of cause and effect between menstrual troubles accompanied by symptoms of peritonism and hyperthermia, and that the phenomena can be explained by irritation of the uterine nervous system.

The Anatomical and Chemical Alterations of the Liver in Scarlatina.—H. Roger and M. Garnier find that the liver is increased in size, of a pale color, frequently mottled with red or purple, and with white, or more rarely red, spots on its surface. The lesions are situated near the porta hepatis; leucocytes abound there, and the cells undergo degeneration, especially fatty degeneration. The amount of albumin is usually increased. Further researches are necessary in order to ascertain what symptoms are caused by this condition of the liver during an attack of scarlatina.

The Rubeoliform and Scarlatiniform Erythema of Typhoid Fever.—Paul Remlinger gives a table of fifty-nine cases showing the time of appearance of the erythema in relation to the onset and to the termination of the disease, the character, duration, and localization of the eruption, the gravity of the disease and its complications, and the method of termination of the eruption and of the disease.

Revue de Chirurgie, March 10, 1900.

Tumors of the Biliary Passages.—F. Terrier and M. Auvray submit tables showing the result of operative interference in sixty cases of tumors of the gall bladder and bile ducts. The mortality in cases of simple cholecystectomy was thirty-five per cent.; in cases of cholecystectomy combined with resection of the liver it was 11.7 per cent. In nearly all cases of radical operation there was return of the tumor sooner or later. Yet in cases of cancer, operation constitutes the only known means of relief, and should be performed unless contraindicated by extension of the disease to neighboring organs, or by cachexia.

Treatment of Renal Retention.—Antonin Gosset urges operation performed at two different times. In the first nephrostomy will cause diminution in the size of the sac, and the fluid which escapes through the lumbar fistula can be analyzed and will indicate the condition of the organ. Should the retention be septic, this preliminary nephrostomy will rest the ureter, and facilitate disinfection of the tissues. In the second the ureteral passage can be re-established either by section of the sac or lateral anastomosis of the ureter to the sac.

Generalized Infected Psorospermosis.—Alexandre Posadas describes a case of this disease. The parasites producing the tumors are sporozoa; they are constantly present in the lesions in man; when inoculated in animals, they produce the same disease and the same lesions as in man, and are constantly present in these lesions. All other micro-organisms are absent from the tumors.

A Study of Burns Caused by Electricity in Industrial Pursuits.—By M. Mally.

Branchial Epithelioma of the Neck.—By Victor Veau.

French Journals.

Semeiological Value of a Painful Point in the Left Hypochondrium, Symptomatic of Gas in the Large Intestine.—Paul Reynier calls attention to a pain often complained of on the left side at the margin of the ribs, or more especially in men at a point opposite the suspender button, and in women causing them to loosen the corsage. Dilatation of the stomach is usually found, and the pain frequently disappears upon the passage of flatus. The pain is at the angle formed by the transverse and descending colon, and is believed to be due to distention with gas. The dilatation of the stomach must be treated, the bowels kept active, and if there are recurrences massage should be given. Two cases are related.—*Journal de Médecine de Paris*, April 1, 1900.

The Diagnosis of Pulmonary Tuberculosis in Young Children.—Dr. Bertherand says the diagnosis of pulmonary tuberculosis in children is based less upon a distinct symptom than upon an ensemble of functional and physical signs; and still this ensemble has only a presumptive value. It is well to employ the more precise means of diagnosis. Tuberculin and artificial serum injections, and especially bacilloscopy of sputum and stomach contents, and as accessory measures radioscopy and radiography, may give important results. It is often necessary to employ them simultaneously, in which way they will control one another.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, April 1, 1900.

The Technique of Pylorectomy.—H. Hartmann and B. Cunéo draw their deductions as to operative measures required from a study which convinces them than cancer of the pylorus extends but little toward the duodenum; that it extends, on the other hand, toward the stomach and particularly toward the lesser curvature. It invades the ganglia especially toward the smaller curvature. In the operation they propose but two ligatures are required to control hemorrhage, one placed upon the gastric coronary, the other on the gastro-duodenalis, after which one can operate rapidly and methodically.—*La Presse Médicale*, March 31, 1900.

Two Very Rare Varieties of Phlegmonous Angina in Infants.—Albert Katz relates an observation of an abscess at the summit of the uvula in a nursing infant which presented all the signs of a retropharyngeal abscess with intense dysphagia, dyspnœa with paroxysmal attacks, etc. All were promptly relieved by incision. The second case was one of peritonsillar phlegmonous inflammation of the tongue in an eight-year-old child. No similar case was found in literature. Paroxysms of dyspnœa came near causing the child's death.—*Le Progrès Médical*, March 31, 1990.

Interlobar Purulent Pleurisy.—Pagliano and Loss relate an instance of streptococcic empyema in which the use of the Marmorek serum was followed by cure, and conclude that in this remedy we possess a means of treatment which is not to be disdained. In many cases of streptococcic infection it may give almost unhoped-for results, and if its action is as favorable in other cases as in this it will not remain a resource of last resort.—*La Presse Médicale*, March 28, 1900.

Isolation of the Tuberculous.—J. Thiénot dwells upon the utility of treatment by sanatoria, of which there are relatively few in France as compared with Germany, where there are now over thirty, with about three thousand beds, capable of caring for ten thousand phthisical subjects yearly. He urges the erection of sanatoria in the country throughout France.—*La Médecine Moderne*, March 31, 1890.

Journal of Nervous and Mental Disease, April, 1900.

A Case of Unilateral Progressive Ascending Paralysis, Probably Representing a New Form of Degenerative Disease.—Charles K. Mills reports a case which he thinks may represent an unusual form of amyotrophic lateral sclerosis. The most probable diagnosis would seem to be that of a slowly increasing degeneration of the pyramidal fasciculi or of the cerebral motor neuron system. A slowly increasing focal cerebral lesion does not seem probable, for in this case the motor fasciculi for the leg and then those for the arms and face were affected. Special and general symptoms of focal lesions, such as tumor, hemorrhage, softening, and abscess, were not present. A degenerative motor neuritis would not be likely first to select the leg and then the arm and face of the same side. The deep reflexes were too exaggerated for a peripheral nerve affection. Functional hemiparesis was improbable from the persistence and progressive increase of the symptoms and the absence of hysterical stigmata.

A Case Presenting Right-Sided Hemiplegia with Hemianæsthesia, Right Homonymous Hemianopsia, Jargon Aphasia, Wernicke's Pupillary Reaction Sign, and Neuritic Pain in the Arm of the Paralyzed Side.—F. X. Dercum reports a case which is of interest because of the association of the above-named unusual number of symptoms. The presence of Wernicke's hemipupillary inaction sign in keeping with the profound hemiplegia, and with the persistent hemianæsthesia, hemianopsia, and sensory aphasia, indicates a most extensive lesion—one involving the entire posterior limb of the internal capsule, adjacent structures such as the thalamus and radiations of Gratiolet, and probably a large portion of the substance of the left hemisphere as far as the cortex. The lesion was doubtless vascular, though whether hemorrhage or embolism it is difficult to say.

Transient Real Blindness in Hysteria.—George C. Harlan reports the case of a woman who complained of loss of vision in the left eye of three days' duration. Every known test was applied, even the application of the modified Graafe prism test, viz., watching the behavior of the eyes behind a prism, but the eye seemed absolutely blind. Ten days later the sight was so rapidly returning that the patient could read with it No. LXX. of Snellen's type at twenty feet. The author divides hysterical blindness into two classes: in the first there seems to be a more or less deliberate deception, a symptom perhaps of "ganglionic insanity," as hysteria has been called; in the second the patients are themselves deceived, and are not capable of conscious vision. The author is half tempted to add a third class, in which blindness is real and absolute, but transient, and without recognizable cause.

A Case of Acute Poliomyelitis Anterior in a Youth Seventeen Years of Age.—Wharton Sinkler reports a case which he says possesses three points of interest: First, the unusual age at which poliomyelitis occurred; secondly, the fact that although there was reaction of degeneration in the anterior tibial muscles of the left leg, there was still good response to the faradic current, and that, although all the muscles of the right leg have regained almost the normal amount of strength, there still remains reaction of degeneration in the anterior tibial group. The third point which is notable is, that there is exaggerated knee jerk in the right leg, whereas two months ago this was entirely absent. The author has seen one other case in which, after recovery from poliomyelitis, there was exaggerated knee jerk.

Landry's Paralysis.—E. W. Taylor and J. E. Clark offer a clinical case and pathological findings as evidence to support their view that the disease cannot be classified as an individual entity. If Landry described a certain disease, they say, it is clear that we must find the pathological anatomy and etiology of this supposed disease and not of some other, or else give up the word as an unnecessary encumbrance to our already overburdened nomenclature. Inasmuch as there is no essential constancy in the clinical symptoms nor in the pathological findings of so-called Landry's paralysis, and inasmuch as the etiology is wholly vague, it is probable that the affection does not represent in itself a process to which the term "disease" may properly be applied.

Annals of Surgery, April, 1900.

On Volvulus in Association with Hernia.—R. L. Knaggs narrates histories of eighteen cases divided into the following classes: volvulus of the hernial contents (cases in which all the intestinal contents are involved or only a part of them), volvulus in which the hernial contents are implicated, but in which the neck and some of the coils lie within the abdomen, volvulus produced within the abdomen by the reduction of the hernia, and volvulus occurring within the abdomen from some predisposing condition more or less directly connected with a hernia. The various operative modifications called for by these conditions are then discussed in detail, and a careful study is made of the mechanical factors leading to the various morbid conditions.

Surgery in the Presence of Sugar in the Urine.—A. L. Fisk believes that while patients with glycosuria are not good surgical subjects, the opinion is growing that with extreme care in the selection of cases and scrupulous perfection in surgical asepsis they must not be denied the benefits of surgical relief. He then gives histories of operative cases, including mammary carcinoma, suppurative appendicitis, and two cases of gangrene of the foot and toes, in all of which, except one of the last two, recovery occurred. Fiske calls attention to the necessity of as little interference as possible with the vascularity of the tissues, and every operation should be planned with this point in view. He thinks it better to cut down upon and ligate the artery in gangrene of the extremities rather than to attempt the bloodless amputation method by means of the Esmarch band.

On the Principles Involved in the Immediate Hermetic Sealing of Aseptic Wounds.—H. O. Marcy makes a plea for the recognition of the vitalized structures with which we have to deal. They should be injured as little as possible. Hence dissection should be clean. But little force should be applied in occluding the largest blood-vessels, and coaptated structures are to be placed at rest so that they furnish a minimum of exudates. Suture material serves a better purpose by being antiseptic rather than aseptic, and for this reason he urges the importance of soaking tendons (which the author prefers) for thirty minutes in a 1:1,000 solution of bichloride, taking the suture directly from the solution as required for use. A strong advocacy is given to the use of iodoform collodion strengthened by a few fibres of cotton.

On the Use of Fixation Plates in the Treatment of Fractures of the Leg.—In this paper by L. W. Streinach, and illustrated by some excellent skiagraphs, the author's personal experience with the fixation plates is detailed in the recital of four cases. An incision is made under ether with its centre over the line of fracture, and the soft parts are retracted, special care being taken not to disturb the periosteum. A small silver plate is then inserted in the shape of a cleat to the flat subcutaneous surface of the tibia, secured by small galvanized steel screws. The wound is then sewed up, though a small gauze drain may be left in to take off the oozing. The plate seems to be a harmless tenant in the leg, and is left until bony union has taken place. It is then removed under local anæsthesia.

Traumatisms Inflicted by Animals.—R. Harvey Reed makes a short but interesting study of this class of injuries, giving two illustrative cases in which trauma was produced by a lion and grizzly bear respectively. He counsels the conversion of all punctured wounds into open ones by means of free incisions. He has had much satisfaction with an evaporating bichloride solution, for which he gives the following formula: Three-per-cent. boracic-acid solution, 80 parts; alcohol, 10 parts; glycerin, 10 parts; and eight drops of a saturated solution of bichloride to the pint. The latter is made by adding two ounces of bichloride to two ounces of alcohol and six ounces of glycerin; of the latter eight drops to the pint equal 1:3,500.

The Relationship between Cholecystitis, Jaundice, and Gall Stones.—A. MacLaren believes that jaundice is a very much over-rated symptom of gall stones, as during the last year he has operated on nine cases of gall stones, in none of which was jaundice present. All of the patients had had colic requiring relief by morphine. In all but one the gall bladder was found inflamed, thickened, and frequently adherent to neighboring organs. He adds some interesting observations on the infection of the gall bladder by micro-organisms which may enter from the bowel or more likely be filtered out of the general circulation by the liver.

Conical Stump after Amputation in Childhood.—C. A. Powers calls attention to the fact that after amputation through the upper part of the arm or leg in childhood, a slow development of a conical condition is physiological and is to be expected because the humerus and leg bones are developed in large part from the upper epiphyses. Parents should be warned at the time of operation of the possibility of such an occurrence.

The Surgery of Gastric Ulcers.—T. W. Huntington describes the operative procedures in two cases, one of perforating ulcer followed by cicatricial contraction of the pylorus and extensive dilatation of the stomach, and the other perforating ulcer with peritoneal extravasation. Reference is made to recent statistical literature on the subject.

Excision of the External Two-Thirds of a Gasserian Ganglion, by the Hartley-Krause Method, after Preliminary Ligation of the External Carotid Artery.—By J. M. Spellissy.

Two Cases of Anomalous Spinous Processes of the Seventh Cervical Vertebræ Articulating with the Scapula.—By J. T. Rugh.

New Operative Table and an Improved Bowl Stand.—By A. Scachner.

The Montreal Medical Journal, March, 1900.

Gonorrhœa in its Relation to Diseases of the Eye.—Frank Buller says that bacteriological investigations have demonstrated that in the early stages of gonorrhœal ophthalmia the gonococci are present only in the conjunctival epithelium, but that later on they penetrate deeply in the subconjunctival tissues. If an early diagnosis can be made the logical inference is that an antiseptic powerful enough to render aseptic the entire epithelial structure should be capable of arresting the disease. The author has the conjunctiva thoroughly washed with perchloride of mercury solution, 1 : 3,000, the patient being etherized; the outer canthus is freely divided, and the lids are thoroughly everted so that every part of the conjunctival sac is exposed, and irrigated with warm water; after protecting the cornea with vaseline, the entire conjunctiva is freely swabbed with an eight-per-cent. solution of silver nitrate, and after a few minutes with perchloride, 1 : 2,000, and lastly smeared abundantly with vaseline and cold borated compresses are applied. This method he has found effectual.

History of Gonorrhœa.—John Macrae says that the first history of this disease which merits any consideration was written forty-five hundred years ago, and that thirty-six centuries of silence intervened. About 1500 A.D., when syphilis had somewhat spent its severity, gonorrhœa again comes into prominence. Paracelsus classed it as a variety of syphilis, an error which passed unchallenged until the protest of Cockburn in 1728. From 1770 onward the Edinburgh school taught with no uncertain voice that gonorrhœa was a disease *sui generis.* In 1870 Neisser, of Breslau, announced that he had found an organism existing in gonorrhœal pus, and since that time the presence of the gonococcus can be decided as "an immoral certainty." Of late years this organism has been found in most of the serous cavities of the body, and it has been demonstrated in peritonitis, arthritis, iritis, and salpingitis; in the pleura, and elsewhere. "The end is not yet."

Acute Gonorrhœa and its Complications in the Male.—A. E. Garrow gives the symptoms of the affection, and a list of the complications, *i.e.*, balanoposthitis, with phimosis or paraphimosis, folliculitis and peri-urethritis with their complications, abscesses and cowperitis, lymphangitis, lymphadenitis, cavernitis, posterior urethritis, acute prostatitis, rarely cystitis, vesiculitis, and epididymitis. The method of treatment which he has found most satisfactory consists in copious irrigations with weak antiseptic solutions; with bichloride or with permanganate of potash, using them in large quantities and hot, at least 115° F. and sometimes 120° F. These he applies by means of rubber catheters, glass catheters, special irrigators, and meatus nozzles. Within the last six months he has followed each irrigation by an injection of protargol, one-half to two per cent., which is retained from fifteen to thirty minutes.

Hammer Toe.—G. A. Charlton describes a case in which the four outer toes of each foot were in a position commonly designated as "hammer toe." Each toe showed marked hyperextension of the first phalanx; the second phalanx was flexed at a right angle to the first, and held so firmly as to give the impression of ankylosis of the joint. Upon dissection no ankylosis was found, and the lateral ligaments were found definitely not to be contracted, in opposition to what has been observed and described in other cases of hammer toe. Upon division of the extensor tendon the toe was straightened out into the natural position. Cases of hammer toe are either congenital, being a distinct condition, or a primary stage in the development of club-foot, or acquired from traumatism producing inflammation, or the long-continued pressure of an ill-fitting shoe.

Gonorrhœa in the Pregnant Female.—J. Chalmers Cameron urges the importance of early diagnosis and energetic treatment in these cases. The cocci may lurk in so many pockets and corners of the genito-urinary tract, the rectum, and the parturient canal, that great care must be taken to turn them out from all their hiding-places. Treatment which does not succeed in doing this will probably fail, because of the lasting properties of the gonotoxin. The expectant attitude cannot be defended. Careful diagnosis, a thorough local examination, persistent treatment, the results being checked from time to time by bacteriological examination, seems to be the line now indicated.

Gonorrhœal Arthritis.—James Stewart gives an account of forty-eight cases. Only six were women. The average age of the patients was thirty years. Only three had a decidedly rheumatic history. To judge from these cases, arthritis is as liable to follow a mild attack as a severe one. The commonest form of the disease was the polyarthritic. These resembled subacute rheumatism. Inflammation began either suddenly or gradually in one joint, and extended to others with moderate fever and constitutional disturbance. Most of these cases when admitted early did well, but at least half were left with partial ankylosis of some of the joints involved.

Chronic Gonorrhœa in the Male.—George E. Armstrong is strongly in favor of dilating all dilatable strictures, and considers that nearly all gonorrhœal strictures behind the peno-scrotal angle are dilatable by the interrupted or continuous method. In a general way he reserves for cutting gonorrhœal strictures of the pendulous urethra, traumatic stricture, and congenital stricture of the urethra. In one case of traumatic stricture involving fully two inches of the urethra, he found it necessary to lay open the stricture area by dissection, and then to form a new floor, as in the operation for hypospadias. The result was entirely satisfactory.

The Edinburgh Medical Journal, April, 1900.

Reflex Salivation from Abdominal Disorders.—F. Parkes Weber writes of the reflex salivation which sometimes occurs in pregnancy, in cirrhosis of the liver, and in various disorders of the stomach and abdominal viscera. Most of these cases, he believes, are examples of what may rather loosely be termed "mistaken reflex action," because they are purposeless. Reflexes excited by abnormal irritation of the gastric and intestinal mucous membrane can all be explained as attempts to clear the alimentary canal of irritating matter. Vomiting, increased peristalsis, and excessive secretion from the bowel, stomach, and salivary glands dilute any irritating matter in the alimentary tract, and get rid of it upward by vomiting and spitting, or downward by diarrhœa. When the same symptoms are reflexly induced by other abdominal disorders, they may be considered as examples of apparently purposeless or "mistaken" reflex action.

Gastro-Intestinal Self-Intoxication as a Factor in Nervous Diseases.—O. J. Kauffmann believes that a certain number of cases of nervous disorder and nervous organic disease are reasonably explicable by gastro-intestinal self-intoxication. What proportion of the cases which are not attributable to other causes may be explained in this way, can be determined only by much more extensive clinical observation. As regards indicanuria, and its importance as a sign of disordered digestion, it must be borne in mind, first, that it is a variable sign, apt to be present one day and absent the next, and that, therefore, value can attach to it when its presence is more or less constant; secondly, that it may well happen that there is much disorder of the digestive processes without the production of indol, and that consequently we must not allow the absence of indicanuria to exclude the possibility of disordered intestinal digestion.

Pathological Amenorrhœa from Other than Constitutional Causes.—F. W. N. Haultain says that in the absence of pregnancy and deteriorated constitutional states amenorrhœa is not a common condition. From a general point of view it may be classified as of two types, primitive and acquired; and from a physiological aspect each may be considered as due to (1) atresia of the canals; (2) uterine conditions; (3) ovarian conditions. In acquired amenorrhœa, that due to impairment of the functions of the ovary, uterus, or controlling nerve centre (the last being perhaps the most frequent and most easily overlooked), treatment is often successful. The constant electric current is satisfactory. Ovarian inactivity is in many cases overcome by the administration of ovarian extract. The usual dose necessary is only gr. xv. per diem, but gr. xl. daily may be administered without untoward symptoms.

Perigastric and Periduodenal Abscess.—N. Soltan Fenwick describes in detail the symptoms and course and results of the formation of these abscesses. As to treatment, he says that as soon as the existence of the abscess can be determined, the cavity should be opened and drained, for every day that the operation is postponed increases the risk of secondary inflammation of the thoracic viscera and perforation of the diaphragm. The abscess is most conveniently opened in the left hypochondrium, care being taken not to disturb the adhesions between the stomach and the abdominal wall, which prevent extravasation into the general cavity of the peritoneum. When the pus is situated in contact with the diaphragm, a counter-opening may be made between the ribs behind, in order to secure free drainage.

Preventive Operation in Acute Inflammation of the Appendix.—Mansell Moullin says that if all the cases of inflamed appendix which come to operation at last were operated upon at once, say before thirty-six hours have elapsed, some lives which are lost now would be saved; and there is no reason to think that any of the patients who are saved now by operation would be exposed to additional risk, while certainly the duration of their illness would be materially curtailed, and the chance of grave accidents setting in considerably lessened. An operation to be preventive must be performed before forty-eight hours from the time of onset, and must not be confounded with operation upon the fourth or fifth day, when conditions are materially different and much more complicated.

On "Washing" Dysenteric Stools.—Kenneth MacLeod describes the process, and enumerates the points of information learned by it. The color of the fluid indicates the amount of blood contained in the evacuations; the size, shape, and character of the feculent masses give information as to the condition, calibre, and tone of the diseased gut; the activity of the digestive process may be inferred, and the character of the ingesta determined; the floating flecks of mucus will show the stage of the dysenteric process; the residuum, especially casts or sloughs, will indicate the nature of the destructive process; and the results of treatment may, to some extent, be judged.

A Case of Murder and Suicide.—By Harvey Littlejohn.

The Bristol Medico-Chirurgical Journal, March, 1900.

Rheumatic Disease of the Cardiac Muscle.—Theodore Fisher writes of the lesions found in the heart in rheumatic cases. It does not require the visual evidence of disease of the heart muscle in cases of pericarditis, he says, to show us that there is poisoning of the cardiac walls. The rapid fatality of many cases is the best evidence of the poisoning, for it cannot be considered possible that mere inflammation of the serous covering of the heart can arrest its action. In some cases there is acute rheumatic poisoning of the heart muscle without any pericarditis at all. Dilatation of the heart has been frequently noticed in cases of acute rheumatism, so that perhaps the mitral regurgitant murmur developing during the course of the disease will often not indicate a lesion of the mitral valve, but be secondary to cardiac dilatation. Weakening of the heart, tachycardia, and mild anginal attacks may all follow rheumatism.

The Spontaneous Disappearance of a Sarcomatous Tumor.—G. Munro Smith reports a case in which the primary lesion appears to have been a lympho-sarcoma at the angle of the jaw. This was extirpated; it recurred, and after an unsuccessful attempt at removal of the recurrent growth, the latter spontaneously disappeared. Ulcers on tonsil and palate and ascites seemed clearly due to malignant disease, yet recovery from both took place. The microscopical examination, the clinical features, and the termination by numerous pigmented tumors, etc., causing death from exhaustion, all this is in favor of the cycle of events being malignant. The late Mr. Greig Smith reported three cases of solid abdominal tumors which spontaneously disappeared.

Russki Arkhiv Patologii, etc., Jan. and Feb., 1900.

The Curability of Syphilis.—V. M. Tarnovski reports fifty cases of syphilis, most of which he saw at the beginning and kept under observation for from twenty to forty years. All cases are excluded in which there was reason to suspect syphilis in the parents, and no case is included in which less than sixteen years had passed since the last symptoms. He concludes from a study of these cases that syphilis is curable in all its stages, but it is in the secondary period that a cure is most frequently obtained. The use of mercury and of iodide of potassium is the main reliance in the cure, but there are other factors which aid in bringing about this effect. Of these factors the most important are a robust constitution and an absence of hereditary or acquired taint of any kind. The natural power of resistance, which varies in each organism, is also an important factor. The danger of syphilis does not reside exclusively in the general lesions produced by the disease, for these are amenable to our present modes of treatment, but in the special localizations and in the so-called parasyphilitic affections.

Orrhotherapy of Streptomycosis.—N. P. Neshchadimenko reports in a preliminary communication the results of a series of experiments in artificial immunization against streptococcal infection. He says that there is no essential difference in the streptococci provoking various diseases in man, but that they are identical in their biological and pathogenic properties. By means of a new method elaborated in the Bacteriological Institute at Kieff, he claims to have prepared a serum, called polystreptococcic, which agglutinates streptococci, attenuates remarkably virulent cultures of these micro-organisms, confers immunity upon animals, and cures those already infected. The details of his method of cultivating streptococci, of increasing and diminishing their virulence, of immunizing animals, as also of the pathogenosis of streptomycosis in man and its orrhotherapy, are now being elaborated by him, and will be published as soon as possible.

Echinococcus of the Brain Complicated by Hemiatrophy of the Face.—V. A. Muratoff reports a case of this nature in a boy eleven years of age, who entered hospital with the following symptoms: Severe headache with a chronic otorrhœa of two years' duration; double neuroretinitis; hemiatrophy of the left side of the face, tongue, and soft palate; weakened sensibility to pain on the same side. The child died at the end of two months, and at the autopsy there was found an echinococcus cyst of the posterior cranial fossa which compressed the protuberance and the bulb. There was marked atrophy of the nucleus of the twelfth nerve on the left side, together with a degeneration of the intramedullary portion of the root of the hypoglossal nerve. There were also atrophied cells in the left nucleus of the facial nerve.

A Case of Pemphigus Foliaceus of Cazenave.—G. M. Nazaroff reports this case occurring in a woman sixty-seven years of age. On the mucous membrane of the palate and of the lower lip there were raw patches, denuded of epithelium, surrounded by strips of tissue which had apparently formerly covered the blebs. On the scalp, the neck, the chin, the breast, and the back there were bullæ of various sizes and denuded patches; these bullæ were red, shining, and moist, and their periphery was covered with delicate epithelial strips. A slight sliding pressure on the apparently normal epidermis was sufficient to detach it from the subjacent tissue. At the autopsy, beyond the changes in the internal organs incidental to advanced age, nothing abnormal was found except the cutaneous lesions.

The Absorption of Bacteria by the Lymphatic Ganglia.—A. S. Egoroff has repeated Halban's experiments, and confirms his conclusions that the time of appearance of bacteria in the ganglia nearest the point of infection varies with the different species. The pathogenic microbes are absorbed by the ganglia less rapidly than the non-pathogenic or the pathogenic in animals naturally or artificially immune. The bacteria are carried through the lymphatic vessels in a free state, and it is only when they have penetrated into the interior of the ganglia that they are frequently englobed by the macrophagi.

The Inoculability of Typhus Fever.—O. O. Mochutkovski reports some experiments made a number of years ago, but not before published, as a result of which he formulates the following conclusions: The primary infection in typhus fever occurs in all probability in the blood. The inoculation into a healthy person of blood taken during the height of the fever produces an attack of typhus fever. The incubation period of the disease thus caused is eighteen days.

The Antitoxic Nature of the Aniline Colors.—G. Gabrichevski reports in detail a number of experiments with fuchsin, vesuvin, pyoktanin, and other aniline dyes to determine their antitoxic properties. He concludes that while the fact of an antitoxic action of these substances is undoubted, the way in which this action is effected is uncertain.

Il Policlinico, March 15 and April 1, 1900.

The Development of Cancer in the Lymphatic Glands.—Concluding an article from a previous number, Oreste Sgambati says that in all cases of mammary cancer there exists, independently of metastasis, a homolateral tumefaction of the axillary lymphatic glands, which differs macro- and microscopically from ordinary acute or subacute inflammations. The glands have the clinical characters of those really invaded by cancer; the first traces of cancer in the glands are usually found in the afferent blood-vessels, and are followed by more or less pediculated vegetations on the wall of a lymphatic space or vessel. Necrosis and the formation of lymphatic infarcts may follow the complete occlusion of an afferent lymphatic vessel, with the fibrification in mass of all the glandular tissue dependent on that vessel. These changes in the glands are due to some toxic influence proceeding either from the retrogressive products of the cancer cells, or from the parasites which may be the etiological factors of the neoplasm.

Generalized Hydroa in its Relations to Polymorphous Erythema.—Angeloni, concluding an article from a previous number, says that from the clinical facts observed it is evident that erythema iris and hydroa are identical: that is to say, that a morphological distinction is justifiable only as a convenience in the differential diagnosis between polymorphous erythema and pemphigus. Hydroa does exist without any intermediate phenomena of erythema, and it is well to recognize this fact, in order not to jump to the conclusion, in these cases, that we are dealing with cases of acute pemphigus.

Relation between Intestinal Putrefaction and the Sterilization of Milk.—Angelo Volpe from the result of experimentation and careful observations concludes that by sterilization the qualities of milk are so changed that its assimilation is rendered more difficult. In the feeding of infants with sterilized milk, what is gained on the one hand by a diminution in the number of bacteria is lost on the other by the fact that only a portion of the milk is digested, the rest remaining in an undigested condition in the intestines, where it gives rise to putrefaction, which is not a harmless occurrence. Rather than submit all milk to this process of sterilization, the author would in most cases make sure that the source of the milk supply is all that it should be, and leave it in its natural condition.

Meditsinskoe Obozrenie, March, 1900.

A Case of Streptococcal Endocarditis.—G. A. Guseff reports the case of a lad nineteen years old, who was brought to the hospital suffering from fever, right-sided hemiplegia, and loss of speech. A year before he had had acute articular rheumatism, following which he suffered from dyspnœa and palpitation of the heart. In about two months he returned to work in pretty fair condition. He was again taken ill about three weeks before admission, and a week later he fell, losing consciousness, and when taken home was found to have hemiplegia and aphasia. On admission he had a temperature of 99.5° F., and a pulse of 98. A diagnosis was made of endocarditis, the cerebral symptoms being due to embolism. Examination of the blood revealed no micro-organisms, but there was a marked leucocytosis with predominance of multinuclear forms. Cultures made from the blood showed the presence of streptococcus pyogenes albus. Two injections of antistreptococcus serum were made. After each there was a fading out of an erysipelatoid eruption on the forearm, but the temperature rose and the general condition was made worse. The parents removed the patient from the hospital, fearing a repetition of the injection, and he died soon afterward.

Malarial Insanity.—Alexander Ivanoff says that malarial psychoses may occur under two forms: (1) Periodical malarial insanity, occurring only on the day of the paroxysm, which may either be accompanied by other symptoms on the part of the temperature, pulse, etc., or be the only manifestation of the malarial infection. (2) Post-malarial insanity which develops after the subsidence of the febrile attacks or during a malarial cachexia. He attributes the occurrence of the psychical disturbance to the direct action of the malarial toxin on the cerebral cortex, or to the poor nutrition of the latter, because of the diminished hæmoglobin and the consequent lessened oxidation. The prognosis of malarial psychosis is very good. The treatment is antimalarial and symptomatic. Six cases are reported.

A New Method for the Closure of a Vesico-Vaginal Fistula.—S. Spasokukotski operates as follows: He passes a loop through the vesical mucous membrane on each side of the fistula, and by pulling on these everts the edges of the opening toward the vagina. Then he cuts into the connective tissue between the vaginal and the vesical mucous membranes. Now the loops are threaded through the eye of a large blunt-pointed probe, which is passed through the urethra, thus drawing the vesical flaps of the divided vesico-vaginal septum into the bladder and approximating the raw surfaces. Finally, the vaginal flaps are brought together by sutures, with their raw surfaces in apposition. The writer reports several cases in which his method was employed with success.

Treatment of Cicatricial Stenosis of the Pylorus.—A. Th. Kablukoff reports two cases of stenosis of the pylorus following cicatrization of gastric ulcer, in which a Heincke-Mikulicz operation was performed with successful result.

A Receptacle for Suture Materials.—By G. Graefe.

Clinical Department.

HOW TO SEND MOIST ANATOMICAL SPECIMENS BY MAIL.

By FREDERICK T. GORDON,

HOSPITAL STEWARD U. S. N., NAVY YARD, LEAGUE ISLAND, PA.

It is often both desirable and necessary that specimens for sectioning should be kept in their appropriate preserving solution while being transported by mail and express, lest they dry out, shrink, and become wholly spoiled. The postal regulations act as a bar to the sending by mail of bottles containing liquids unless certain precautions are taken, and it is sometimes very difficult so to pack specimens that they may arrive at their destination in the proper condition. Necessity being the mother of invention, the writer had recently to find a means of surmounting these difficulties, and the method used has so far given perfect success. It is, in brief, as follows:

A bottle is to be selected of a capacity twice that of the bulk of the specimens to be mailed, and fitted with a sound cork. The specimens are taken out of the preserving fluid (alcohol, etc.) and rolled up in pieces of lint, turning the ends over and twisting them tight; then this bundle is dipped into the preserving fluid and any excess squeezed out. The roll is placed at the bottom of the bottle. The next specimen is prepared in the same way, and so on until all are wrapped up in their saturated coverings of lint and packed into the bottle. Then a wad of absorbent cotton is taken large enough to fill the remaining space in the bottle, dipped into the fluid, and the excess pressed out, and then it is packed snugly on top of the rolled-up specimens. The bottle is corked tight and sealed with paraffin or wax, wrapped in paper in the usual manner, and addressed for mailing. There will be no liquid to spill if the bottle is broken.

The rationale of this method lies in the presence of an atmosphere saturated with the vapor of the preserving-fluid in the bottle, it thus being impossible for the solution to evaporate from the specimens and leave them dry and hard. The method is as applicable to a specimen half a cubic inch in size as to an entire tumor or organ; the ease of its details and the cheapness are arguments in its favor, to say nothing of the convenience in being able to send the most delicate specimens absolutely safely by mail or express. If the bottle is not uncorked, the contents will preserve their freshness endefinitely; the writer has had a bottle with two sections imbedded in celloidin for a month before opening, and the celloidin was as fresh and in as good condition when opened as when packed. Moreover, by making the package weigh lighter, there is quite a saving in postage.

It is also suggested that the same method might be of use in preserving large specimens when it is impossible to secure enough preserving fluid to cover them at the time. They should be wrapped in lint saturated with the appropriate fluid, and packed into a bottle or jar with a wad of absorbent cotton soaked in the same fluid and corked tightly.

Ununiting Fractures, it was thought, might be beneficially influenced by thyroid opotherapy, but the experiences of Guinard, Poirier, and Rochard oppose this view.—*Gaz. Hebdom.*, January 4th.

Correspondence.

MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The Prolongation of the War is now, I think, inevitable. At the beginning of fighting, Christmas, 1899, was fixed by the British public as the probable date for the cessation of hostilities. When the fall of Kimberley or that of Ladysmith was expected to occur any day, opinion flew to the opposite extreme and the British spoke of preparations to carry on a guerilla war for ten years if necessary. Then came Lord Roberts' victories, and Easter, 1900, was popularly accepted as a convenient and fitting date for unfurling the Union Jack at Pretoria. But by the end of the first week in April it has become obvious that the Boers may be able to make effective resistance for at least twelve months, though, of course, they may decide not to do so. But Lord Roberts cannot move until his cavalry is remounted; for without cavalry he cannot clean up the Orange Free State behind him, while he dare not go farther forward while his lines of communication are so seriously menaced as Colonel Broadwood's recent experience and the disaster to the Irish Rifles show to be the case. A long and waiting game—just the game to allow the Boers time to recover their courage and reorganize their defences—is forced upon the British commander-in-chief. The medical aspects of this prolongation of hostilities are obvious. The British troops—a large proportion of whom are quite young men unused to campaigning or severe climatic influences—will have to spend the inclement season of the year under canvas or actually fighting; and camps, the sites of which will be dictated by other than sanitary considerations, will have to be formed. It is certain that there will be a great increase in sickness among the invading troops, who, save when beleaguered and actually suffering from hunger, have so far enjoyed a remarkable immunity from disease. It is almost certain that as the South African winter draws on there will be among the soldiers of both sides many more cases of pneumonia, typhoid fever, and malaria, and when this occurs the medical arrangements that so far have been sufficient may fall terribly short of the ideal. For there will be, perhaps and most probably, stubborn fighting as well as much sickness. Hitherto on the Boer side the losses have been small and the medical care required small also; while the British Royal Army Medical Corps, supplemented by excellent civilian aid, has proved competent to keep abreast with the demands of the much more numerous English wounded. But if many victims of epidemic sickness are added to the same proportion of wounded men in the future, the English medical staff will require much augmenting. I think it should be reinforced already.

Sickness among the Boer Prisoners.—There is a great deal of sickness on board the transports lying off Simonstown, in which the Boer prisoners are confined. Typhoid fever and measles have broken out, and upward of two hundred cases are serious ones, while at the end of March two or three deaths occurred daily. Everything has been done for the sick that skill and humanity can suggest.

Expanding Bullets.—That some of the Boer commandos are using expanding bullets has been proved by the actual finding of such bullets upon prisoners and in deserted laagers, but the changed character of the wounds of the British soldiers at Paardeberg would have suggested this without further evidence. Many of the wounds involving soft parts only have lately exhibited characters quite out of keeping with the injuries inflicted by ordinary Mauser bullets, while primary amputations have become more numerous as a result of the increased difficulty of keeping the wounds free from suppuration. Mr. G. H. Makins, one of the civilian consultant surgeons to the British forces, has made some pertinent remarks upon this point, and his evidence will convince all fair-minded people that the British complaints as to the use of expanding bullets have not been unfounded.

The Irish Hospital is located at Naauwpoort, and a contingent under Dr. George Stoker has gone up to De Aar.

The Hospital Ship "Princess of Wales" has been the subject of much adverse criticism. I have already referred to the unfortunate circumstances attending her start. She left Tilbury dock on November 23, 1899, but had to stop almost immediately through some accident. She started again and had to put into harbor at Sheerness. There nothing wrong could be discovered, and she went to sea and arrived at Cape Town on January 8, 1900, taking forty-seven days to do a journey which ordinary transports do in a fortnight. At Cape Town certain repairs were found necessary, and all the electric lights had to be overhauled, and the return journey to England occupied nearly as long as the journey out. To some extent the long time occupied is accounted for by the fact that the *Princess of Wales* is only an eleven-knot boat, but there seem to have been considerable carelessness and negligence as well, into which there will be an official inquiry. The practical utility of using such a slow vessel to transport the sick and wounded is very doubtful, and most medical men at the seat of war consider that the value of hospital ships is mainly as stationary hospitals. Well-found transports doing the journey from Cape Town to England in a fortnight are much better for conveying the sick, while operating-theatres, *x*-ray chambers, etc., are not required, as no patients are sent back to England until their condition is diagnosed and its acuter stages relieved. As hospitals, the hospital ships do splendid work. The *Nubia*, for example, out of six hundred and seventy-four cases discharged has sent back four hundred and forty-three to resume duty at the front.

UNRESTRICTED DIET IN TYPHOID FEVER.

To the Editor of the Medical Record.

SIR: The tenor of the article in the MEDICAL RECORD of January 6, 1900, by Dr. Morris Manges, on "The Diet in Typhoid Fever," is so much in accord with the extensive, though not tabulated experience I have had out here in Asia that I gladly add my mite of confirmation to it. In a communication to your journal which was published in the issue of February 5, 1898, I wrote: "Affections that would confine Anglo-Saxons for two weeks are thrown off here in half the time. Whether no restrictions as to food in fevers, and a little more trusting to nature than is usual, have anything to do with it or not, is an open question."

I have long been of the opinion that an unrestricted diet in fevers—and I came first to allow it because I could not help myself, treating so many in their homes and with them so ignorant of even the simplest measures—I have come to think that an unrestricted diet, trusting to the craving of the patient largely, instead of doing harm actually does good. I cannot assert that many of my cases were the usual typical text-book typhoid-fever cases. On the contrary, most of them seem to be mixed. The type of which there has been quite an epidemic the past month or so is of quite a different character from that which was prevalent this time three years ago, but the very general recovery under quinine, phenacetin, and unrestricted diet is a marked feature in common. And while it is true that by far the most of the cases are malarial, I feel sure that many would have developed into what we know as typical typhoid if they had had a chance. I lately treated in one hovel five patients who were taken down, one after the other, with what, while I would not call it typhoid here, is what I feel sure, in an American, would have been that disease; and I am inclined to think that the free feeding of rice paste and other such indigestible (?) stuffs so modified the disease, as we note in the reports of Dr. Manges has been done, that its typical character never came out.

I wish to report the success of an ordinary and a liberal diet not only in fevers in general and typhoid in particular, but also in membranous enteritis as we have it rather commonly among Americans out here. The restricted diet reduces the strength of body and of mind so much that what might be thrown off in a comparatively short time, and which has done so in the cases in which it has had opportunity in full diet, has run on for months under the old plan. This subject has been well elucidated by Dr. Max Einhorn in the issue of January 28, 1899, and I am merely reporting clinical experience corroborating his plan of treatment.

Patients who date their recovery from fevers from the time they surreptitiously obtained some forbidden food are known to all of us, and one whom I recall, who attributed his recovery from yellow fever to molasses cake which he hid in his bedclothes, is in point. Out here in Asia they do not have to sneak it in, but their friends give them anything they want, and as yet, I must say, I have not seen so much evil resulting from it as I have good. This may not be scientific and it may shock the laboratorians, but it is fact, and if you wish to pass it by with the thought that Asiatics are different from Anglo-Saxons, very well. All I know about it so far is that they recover from fevers under unrestricted diet and very simple medication, with a promptness and an ease which I longed to see manifested in such cases in private practice in the United States before I came out here to the shining Orient. As everything else—ventilation, or rather, the lack of it, huts low on the ground (though they have hot floors, which must be a good thing), no drainage, invariable crowding, and filth in general—is against them, there must be something greatly in their favor, for their weak constitutions, rice fed, cannot count for much; so for the present, and as the drugs used are so simple it can not be they, I will say it is the unrestricted diet which is the secret, and so I will go on that presumption until some one shows me my mistake about it.

J. Hunter Wells, M.D.

Pyengyang, Korea, February 27, 1900.

A NAVAL ENCOUNTER IN THE PHILIPPINES.

To the Editor of the Medical Record.

Sir: Generally little is interesting in the detail of a normal case of labor, but it is different sometimes in our tropical possessions, as the following tale will show. It is a perfectly true "yarn," and I merely "tell the tale as told to me," leaving comments to those who read.

It was after mess at district headquarters in the quaint town of Zamboanga that a handsome young naval officer, sitting with us, gave his unique experience. He had been stationed at a place called Balabac, near the most southern end of the Philippines, with a small detachment of sailors to guard a lighthouse. One of his men having a slight wound on a foot, the officer had been furnished with dressings for it, and, seeing him apply these dressings, the natives believed he was "el medico." It should be said this young gentleman is one of those highly favored individuals who fear naught and are ever ready to go where work is hardest or most dangerous.

We were sitting on our veranda enjoying the moonlight on the water and our after-dinner cigars, when one asked our naval guest to tell his experience as a doctor. Briefly stating the reason for his being at Balabac and the dressing of the wound above referred to, he continued:

"But all I could say would not make the natives believe I was not a doctor, and one evening a man came to me and said his wife was going to have a child, and would I come and help her get rid of her cargo. I refused, and he persisted, putting down my assertions of ignorance to modesty; so at last I gave way, and we got under way for his shack. When we entered, the woman was on the floor. She got up shortly and walked up and down, seemingly in a good deal of pain. By and by she lay down on the bed, an ordinary bamboo bed, and sung out something I did not understand, for I know but little Spanish, and she appeared to heave more than before. Watching, I saw the big lump in her belly went down a bit with every heave, but came back again as big as ever, so I concluded something had fouled inside, and some help was necessary, and I told the husband to board and push, not punch, with his knees on the top of the lump. He did —and for fair, and evidently cleared the jam below, for before long the kid's head came out, and it began to yell. So did the mother. I took hold of the young one, and it was easy enough to finish the launch after his head had come clear.

"There was a string that came along that I did not know what to do with. However, I took up the slack so as to give the youngster room to swing in, and then saw I must cut him adrift. How long a line to give him was a puzzle, but I decided he would ride all clear if he had a line the length to his knee; so measuring I stood by to cut. Then I thought if I let all go the line might unstrand, so I got some stops ready, making them out of heavy thread. Now how many stops to put on was another question; so, to guard against any chance of the line parting, I put a stop about every inch and cut away between the seventh and eighth. The kid being all clear, I shoved it over to an old woman who was in the room.

"For all the child was away the lump did not go down, and I thought there might be more inboard. I had stowed the fast end of the line back where it came from as well as I could; but now to find out if there was a consort. A little girl was in the room, and, cutting her nails so they could not tear, and disinfecting her hand and arm, for I had brought my kit along, some permanganate, two or three darning-needles, and a pair of scissors, I told her to go up in there and see if she could find anything. She said she had hold of something, and, being directed to haul away, she fetched out some liver. Told her to see if anything else would come away, and I kept her at it until we had a big heap on the floor of liver and intestines. I was a little uneasy for fear we had hauled out everything inside of the woman, but, as she seemed easier and the lump had gone down, I considered that all the fixings had not fetched away, so I washed down decks, put the old woman on watch, went back to quarters, and turned in."

"And—and did the mother and baby live?"

"Oh, dear, yes! But I don't want any more like cases. Say, doctor, how do you fellows get on in such foul-weather work?"

L. B.

Two Drops of Spirit of Camphor on the toothbrush will produce a fresh feeling in the mouth and prevent sore tongue, gums, etc.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, April 9, 1900.

Charles N. Dowd, M.D., Chairman.

Sarcoma of the Sphenoidal Sinus, Removed Three Years and Eight Months ago Without Recurrence.—Dr. Joseph A. Blake presented this case, that of a woman twenty-four years of age, who had been admitted to the Harlem Hospital in July, 1896. He had first seen her on August 18th. At that time the left nasal fossa had been completely filled with a large tumor, but there had been no implication of the muscles of mastication. On August 20th, a portion of the tumor had been removed for examination, and it had been found to be a round-cell sarcoma. After previous ligation of the external carotid, the operation for the removal of the tumor had been undertaken a few days later. The tumor had been friable and had been enucleated easily with the fingers. The woman had made an uneventful recovery, and had left the hospital in two weeks. The vision of the left eye was perfect. There had been no eye symptoms except a slight diplopia when not wearing glasses.

Ligation of the Subclavian Vein for an Arterio-Venous Fistula.—Dr. John F. Erdmann presented a young man upon whom he had performed ligation of the subclavian vein for an arterio-venous fistula, the result of a gunshot wound received in August, 1898. The bullet had lodged in the supraspinous fossa, and had been removed a few days later. At the operation it had been found necessary to saw through the clavicle. The communication between the artery and vein had been about one inch and a half in width. The functional result had been perfect, so that his injury in no way interfered with his occupation, which was that of an acrobat.

Persistent Suprapubic Fistula following Lithotomy on a Prostatic; Cured by Bottini's Operation.—Dr. Willy Meyer presented a man aged forty years, who had come under his care in November, 1898, with a urinary trouble that had existed since 1891. Physical examination had revealed the presence of vesical calculi and a moderate prostatic enlargement. There had been at this time a very marked catarrh of the bladder. He had opened the bladder from above on November 25, 1898, removing three rather large stones. The bladder had been in wretched condition at the time, and as a result some tissue had sloughed away. At the end of the fourth week the patient began to pass urine through the natural channel, but a fistula persisted. When seen on October 5, 1899, the man stated that only about half of the urine passed through the normal channel. On October 11th three incisions had been made into the prostate, according to the Bottini method, and without the slightest reaction resulting. The patient soon began to pass a much larger quantity of urine through the normal channel, and less through the fistula. The latter had been tortuous and funnel-shaped, and efforts to secure its closure by injections of balsam of Peru had failed completely. He had then introduced 200 c.c. of water into the bladder, and had followed this by ♏ xv. of pure carbolic acid. Alcohol had next been introduced to neutralize the acid. As a result of this treatment the fistula had healed promptly.

Removal of Half of the Tongue.—Dr. B. Farquhar Curtis presented a man, sixty-two years of age, having a negative previous history. He had used a pipe moderately. About September 15, 1899, he had noticed a small fissure on the left side of the tongue, apparently due to the irritation of a sharp tooth. He had been admitted to St. Luke's Hospital in February, and on the 22d of that month the operation had been done. The Kocher incision had been made below the jaw and a flap turned up, but left attached. The mouth being held open with the Whitehead gag, the tongue had then been drawn forward and split, and half removed. All of the tissues in the floor of the mouth had been removed at the operation. The patient had made a very rapid recovery. The tip of the tongue had been turned around to one side and secured with three or four sutures in order to avoid the disagreeable narrow point left. Although it was only six weeks since the operation, he had regained the use of his tongue, and could talk fairly well.

Removal of Half of the Tongue with Removal of the Tonsil.—Dr. Curtis also presented a man of sixty years who had been admitted to the General Memorial Hospital on December 15, 1899. At that time he had been suffering great pain; the saliva had been dribbling from the mouth, and there had been a deep ulcer at the tonsil extending over to the root of the tongue. However, the mouth could be freely opened, showing that there was no involvement of the pterygo-maxillary parts. The operation had been done on December 7th, beginning with the Mikulicz method. The vertical incision had also been made over the carotid. After separating the periosteum the ramus had been divided, and twisted out of its socket without any division of the soft parts above. This operation had always given him free access to the tonsil, and perfect control of hemorrhage. With the finger in the mouth, hemorrhage could be stopped entirely, or the bleeding point could be turned out and secured. This method of operating, particularly in elderly people, was far better than by dividing the jaw. The growth had been cut away, including the entire tonsil and wall of the pharynx. The tongue had been found extensively involved, and hence it had been removed by the method of splitting it and dividing it at the root. The man had made a rather slow recovery, but the result was good. This method of operating seemed to him far better than the splitting of the cheek or dividing the jaw vertically as was done so often.

Resection of the Rectum and Anastomosis by Maunsell's Method.—Dr. A. A. Berg presented a woman who had been admitted to the Mount Sinai Hospital on September 11th with a history dating back about eighteen months. For a few weeks previously blood had been passed in the stools. She was slightly cachectic. About three inches from the anus the rectum was constricted by a tumor. The growth was movable over the sacrum, and the vagina was not involved. On September 15th, under chloroform anæsthesia, he had removed the rectum. He had first cut down upon the rectum, and freed it up to the peritoneal reflexion. He had then opened the peritoneal cavity and drawn down the peritoneum and sigmoid flexure. He had next closed the peritoneal cavity before opening up any channels of possible infection. The superior hemorrhoidal artery had been ligated and divided so that there had been almost no loss of blood. Having resected about six inches of the rectum the proximal end of the rectum had been inverted into the distal end by the Maunsell method. The patient had been in bad condition at the time, and hence this method of inversion had been adopted as the most rapid and the safest under the circumstances. The patient had rallied well from the operation, and there had been no leakage after the third day. The patient had insisted, however, on lying on the back, and as a result there had been a marginal necrosis, and, on the sixth day there had been a fecal discharge from the opening on the posterior margin of the anastomosis. On December 11th Dr. Gerster had operated to close the fistula. The mucous membrane had been dissected free and inverted, and the fistula closed with the Lembert suture. There was now considerable induration at the site of the anastomosis, but not so much as had existed some time ago. It was possible that some of this induration was due to a recurrence.

A Rapidly Recurring Carcinoma.—Dr. George E. Brewer presented for Dr. H. Lilienthal a woman who had been admitted to the Mount Sinai Hospital on September 17th with a marked carcinoma of the left breast and glandular involvement. On September 26th the radical operation had been done, including the removal of the pectoral muscles; yet on January 31st she had been readmitted with a recurrence. At this time she had been found in very poor condition. Dr. Mundé had done a double salpingo-oöphorectomy, and since then improvement had been very marked and rapid.

Dr. T. H. Manley, speaking of Dr. Erdmann's case, commented upon the excellence of the collateral circulation after this operation, and also upon the admirable shoulder action that the man was said to have had even while there had been only ligamentous union in the clavicle. In this case the lumen of the vein had not been occluded. The collateral circulation had been so well restored that the radial pulse could be felt on that side eight months ago.

Dr. Willy Meyer said that in cases like those presented by Dr. Curtis he had been accustomed to do a tracheotomy and insert a tampon cannula, provided the patient was operated upon in the ordinary recumbent position. With the Kocher operation there was great risk of the blood entering the trachea.

Dr. Erdmann remarked that by the use of the Trendelenburg position the necessity for a preliminary tracheotomy was avoided.

Dr. A. A. Berg said that recently Dr. Gerster had done a resection of the superior maxilla for a retronasal sarcoma, and had done a low tracheotomy. Following the latter operation there had been an inflammation between the pericardium and the pleura, and, as a result of this process in the mediastinum, the patient's life had been in great danger for some time. This was another reason for avoiding tracheotomy in such cases.

Dr. William B. Coley thought that in some cases tracheotomy greatly facilitated the operation. In a case that he had presented to the Surgical Society a preliminary tracheotomy had been done, the glands of the neck removed, and the linguals tied.

Dr. Franz Torek said that if one wished to prevent blood from running down into the trachea it was not sufficient to lower the head slightly, but the head should be allowed to hang down completely over the end of the table. This was not the ordinary Trendelenburg position.

Dr. Charles N. Dowd said that by the method of operating employed in Dr. Curtis' cases hemorrhage was almost entirely avoided by the ligation of the lingual arteries in the first stage of the operation; hence there was but little reason for doing a tracheotomy. He had seen the operation on Dr. Curtis' second case, and the hemorrhage had been under full control. He could not but think that the danger of allowing blood to run into the throat had been exaggerated, especially in view of the many cases of operation on children suffering from adenoids.

Dr. James P. Tuttle, referring to Dr. Berg's case, said that while he could not say positively that this was a recurrence, there was present what he had seen in every other case in which he had used the Maunsell method, *i.e.*, a stricture. This stricture was very much more marked by the Maunsell method than by the end-to-end method or by the use of the Murphy button. If after the gut had been brought together by the Maunsell method, or by end-to-end union, a large-sized silk suture was passed into the lower rectum and brought down and sutured rather tightly into the edge of the skin wound, the parts were relieved from tension. If this was done there was very much less risk of fistula. This anchoring suture could be cut away in four or five days. His own three cases, and the one just reported by Dr. Berg, in which the Maunsell method had been employed, were certainly very discouraging for those desirous of using this method.

Dr. Manley said that in one case of recurrent carcinoma of the breast which had reached the operable stage he had adopted this plan of removing the ovaries and tubes, although the woman was forty-seven years of age. The operation had been followed by a very decidedly beneficial effect on the growth in the breast. He had also followed the suggestion of the originator of this plan, *i.e.*, to administer after the operation the thyroid extract, and he thought the result had justified its use.

Dr. Coley said that the improvement in these cases following the removal of the ovaries seemed to him to be entirely explicable by the change in the blood supply. He did not think there was a single case on record in which the improvement following this operation had been of sufficiently long duration to warrant one in considering it a cure.

The Relative Bearing of the Conjoined Tendon and the Internal Oblique Muscles upon the Radical Cure of Inguinal Hernia.—Dr. Joseph A. Blake read a paper with this title. He said that by the conjoined tendon was usually understood the insertion of the lower fibres of the internal oblique and transversalis muscle, extending along the ilio-inguinal line laterally for a short distance. As a rule the lowermost fibres of the internal oblique did not form a part of the conjoined tendon. The speaker said that he had made a series of observations in the dissecting-room on twenty-five subjects, and had found that the conjoined tendon never extended on the internal surface of the rectus more than five-eighths of an inch. In all cases it consisted only of scattered muscular fibres. The true conjoined tendon was ordinarily such a weak affair that it was negligible in operations. In the radical cure of hernia the main reliance of the surgeon must be the external oblique. As a rule it was futile to attempt to draw down the transversalis aponeurosis. The author closed his paper by a consideration of various operations for hernia, and the parts usually divided in the incision, as on this point, he said, there had been some confusion in the published descriptions of the operations.

Dr. William B. De Garmo said that in the Bassini operation he had been in the habit of separating the internal oblique from the fascia beneath and the external aponeurosis above, so that it came down to Poupart's ligament without undue tension. He had not felt that it was necessary in any case to split the rectus. Even in the largest hernias he had succeeded in closing them by the Bassini method pure and simple. His first puncture of the internal oblique and transversalis was made considerably higher than that of many other operators. He did not cut the muscular fibres passing above the cord; he stripped them up and tried to preserve them. He had operated upon over six hundred unselected cases, and there had been only six recurrences. These patients had been of all ages—from five months to extreme old age.

Dr. Coley said that the cutting of the fibres of the internal oblique had always seemed to him a great defect of the Halsted method. In the Bassini operation, as he had done it, great care had been taken not to cut these fibres. By thoroughly freeing the apo neurosis over the internal oblique, and bringing the internal oblique from the transversalis fascia below, he had never experienced any difficulty in bringing the fibres down easily to Poupart's ligament. The only conditions in which Bloodgood's operation seemed indicated were in cases of large direct hernia. Even in the few cases of this kind that he had had there had been no difficulty in securing good apposition of the parts and firm union without splitting the rectus. Such division of the muscle seemed to be called for in only a very small number of cases.

Dr. J. P. Tuttle asked what the drawings exhibited by Dr. Blake showed that had not been brought out by Alexander H. Ferguson in his paper published last June.

Dr. Blake replied that in Dr. Ferguson's paper it had been shown that the internal abdominal ring was normally situated a considerable distance lateral to the insertion of the fibres of the internal oblique. The paper had been entirely upon the anatomy of the internal oblique muscle. Dr. Blake's paper, on the other hand, was intended to show just what was meant by the conjoined tendon.

Preliminary Report and Demonstration of a New Method of Sterilizing Catgut.—Dr. C. A. Elsberg presented this report. He said that there was much difference of opinion regarding the relative value of the non-absorbable ligatures and the absorbable ones. The use of catgut had been considerably curtailed by the difficulty of uniformly securing complete sterilization without interfering with certain properties of the catgut. Sterilization by dry heat had been recommended, but time, care, and special apparatus were required. Most of the fluids that had been used for this purpose were inflammable, or their vapors were, so that they must be boiled in special apparatus. Formalin catgut was often excellent, but under the same conditions of preparation it was sometimes soft and strong, and at other times hard and fragile. This catgut was absorbed somewhat more slowly than that which was prepared by other methods. Prolonged immersion in dilute solutions of antiseptics required time, and the catgut so prepared was not always reliable. Sterilization by dry heat was impracticable. The requisites for good catgut were sterility, strength, softness, and pliability. In the method about to be described he had made use of a very well-known chemical principle, *i.e.*, that animal substances were insoluble in solutions of those drugs by which they were themselves precipitated. Thus, ammonium sulphate was precipitated by albumin, and therefore albumin was insoluble in solutions of ammonium sulphate. This substance was made use of in this connection, and certain hitherto unknown properties of this substance had been discovered and applied in the new method of sterilization about to be described.

Technique.—The fat should be removed from the catgut by immersion for forty-eight hours in a mixture of one part of chloroform and two parts of ether. The catgut should be wound tightly in a single layer on spools. The chloroform and ether mixture was then allowed to evaporate. The spools were next boiled from ten to thirty minutes in a hot saturated solution of ammonium sulphate in water. This solution was made by adding chemically pure ammonium sulphate to boiling water until saturated or almost saturated. This salt was a neutral salt which became acid on boiling. It boiled at 220°–226° F. When the spools were removed from the boiling solution, some of the salt crystallized out upon them, but this was removed by a momentary immersion in a cold or warm sterile water. It might then be preserved dry, or in alcohol. Careful experiments showed that the catgut was as strong as before treatment, and sometimes stronger. It was readily absorbed in the tissues in from four to eight days. Bacteriological experiments showed that the catgut was always sterile after boiling in the ammonium-sulphate solution for five minutes. The catgut could be chromicized by boiling it in a chromic-acid solution of the desired strength. It was probable that catgut could be made more or less absorbable at will, depending upon the strength of the chromic-acid solution. His experiments on this point were not yet completed. Ordinarily the catgut should be boiled for twenty or thirty minutes in a saturated solution of ammonium sulphate in a 1 : 1,000 chromic-acid solution. The ammonium-sulphate solution could be used over and over again. As this salt costs only fifteen to twenty-five cents per pound, the method could not be said to be expensive; moreover, the solution was non-inflammable, and the method was so simple that no skill or elaborate apparatus was necessary. As a rule, the catgut should be boiled in the saturated aqueous solution of ammonium sulphate for from ten to twenty minutes. A method founded on the same principle, though somewhat modified, could be applied to the sterilization of sponges or other material of a similar nature.

Dr. George E. Brewer said that he had made some tests with this catgut in hospital practice, and had found it very soft and pliable, and exceptionally strong. The method was so simple that the profession should feel greatly indebted to Dr. Elsberg.

Dr. Willy Meyer said that for many years he had been accustomed to prepare his catgut by immersion in a 1 : 1,000 watery solution of bichloride of mercury, and preserving it in alcohol. However, the method just described seemed to be more in accordance with modern ideas of aseptic surgery. He would like to know if the raw, cheap catgut could be sterilized in this manner.

Dr. Blake said that it was admitted that to insure perfect sterilization there should be hydration of the albuminous elements, and hence the objection to dry sterilization or to boiling in alcohol. The method just presented subjected the albuminous materials to this process of hydration.

Dr. Elsberg said that he had tried a great many different grades of catgut, obtained from various manufacturers, and the bacteriological results had been absolutely identical in all of them, though the number of germs in these different grades had varied very greatly. It was important to wash out the ammonium sulphate after boiling, by immersion and agitation either in sterile water or in a solution of bichloride or of carbolic acid. This catgut had been used by Dr. Gerster in several herniotomies and in one very extensive radical operation on a carcinomatous breast in which over one hundred ligatures had been used, and the results had been perfect.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, February 12, 1900.

Robert F. Weir, M.D., President.

Inaugural Address: Remarks on the Formation of an Artificial Anus (see page 661).

Report of a Case in which the Operation was Done, with Remarks.—Dr. W. Gill Wylie, reported the case of Mrs. N. M——, aged forty-five years, who had been married twenty-five years. Her family history was negative as to cancer. Her general health had been good. At sixteen years of age she had had typhoid fever. She had had no intestinal affections previous to the present trouble. During May, June, and July of 1898 she had chronic intestinal obstruction, followed by jaundice in August. She had, at that time, vomiting, obstipation, and a great deal of pain in the abdomen. The jaundice slowly disappeared. In September, during an attack of acute obstruction, she was operated upon at Clifton Springs. She had a left inguinal colostomy performed, and the surgeon thought the obstruction was due to "bands." In November, 1898, an exploratory lapatotomy was done by one of the surgeons. He found a tumor of the bowel as large as a goose-egg in the splenic flexure of the colon, and the artificial anus was apparently made in the hepatic flexure. He thought there was a carcinoma of the gut, and closed the incision. Since then the patient had been perfectly well up to four weeks ago (the history was taken July 5, 1899). Then she began to have pain in the left side and back, which became constant and caused her confinement in bed. There were no bladder symptoms, no chills, no nausea, no constipation, but the temperature ran daily between 99° and 103° F. On July 9, 1899, operation was performed. Aspiration brought pus; then a free incision was made in the lumbar region and about two quarts of very foul-smelling pus was evacuated. A small sinus apparently communicated with the bowel. With the hand inserted into the cavity nothing could be felt but an apparently small stump of the left kidney. The wound closed up by granulation. On January 11, 1900, she returned and the artificial anus was closed. The bowel was freed from the edge of the skin and separated very carefully downward, freeing the fascia without opening the peritoneal cavity. The mucous membrane was first stitched, then came the muscles; and finally Lembert sutures of silk were introduced into the peritoneum. The fascia and abdominal wall were closed in the usual way with silk.

Discussion.—Dr. Robert Abbe said that if an artificial anus could be made to contain fluid this would be an admirable procedure. To-day the operation was much more often done than a few years back, especially when a bad cancer was situated below. If such a procedure could be resorted to he believed that it should be done in every case of inoperable cancer, in order to give patients better health. His own experience had been with the Maydl method, which he found very satisfactory; but in the future he certainly would adopt Dr. Weir's method. Maydl's method had certain advantages; for instance, in most cases the operation could be done under cocaine anæsthesia; probably one-half of all the cases could be done in this way. He had resorted to the use of the intermuscular method, but it did not seem to him to be of great value, having certain disadvantages; the two ends of the intestine could not be brought through the intermuscular layer with the same satisfaction as to the future closure of the opening as when brought out through the end of the wound. If it was desirable to get the two ends separate we must go through the deep muscular layers of internal oblique and transversalis muscles, because, when the two ends were brought out of the wound, there was not enough room to unite the skin well together. Returning the lower end of the intestine was the most popular method, and he had adopted it in the last two or three of his cases. This got it out of the way; it was perfectly innocent; the slight secretion of mucus discharged itself. Inverting the lower end, at the same time handling the upper end, was not easy in cases of stout people; sometimes extensive epiploic masses became very troublesome; if the attempt to invert was made, the question arose, whether it could be done satisfactorily. The ends popped out; if they were cut off there was slight hemorrhage; therefore, with fat people he thought it was very difficult to invert. The question of circulation should not be overlooked in bringing out the upper portion of the bowel; occasionally gangrene of the distal end had occurred because the circulation had been none too good.

Dr. William B. De Garmo said his experience had been largely mechanical in trying to prevent leakage. He appreciated the importance of trying to secure some operation that would aid in preventing leakage of the bowel. The appliances usually shown had been in the form of a truss with a hard-rubber pad; he thought the soft-rubber pad better. He had labored many hours in trying to adjust appliances to prevent soiling, but with poor satisfaction. He believed the operation suggested was a rational one.

Dr. Arpad G. Gerster said that if we would think back twenty years and recall to memory the status of colostomy, and compare it with what it was to-day we all must see an enormous revolution in the operation. Colostomy was then considered a dreadful thing. It was then only a palliative measure—to relieve patients of uncontrollable vomiting. To-day it was one of the most useful operations. To illustrate: one experience he had was in the case of a man who was a waiter in Delmonico's for twelve or thirteen years; he waited on his various customers with an artificial anus in his groin, and none of them knew of it. He was able to attend to his business perfectly well. He recalled experiences with lumbar colostomy years ago, when the surgeons dreaded coming in contact with the peritoneum; the peritoneum tyrannized every surgeon. Often the old war-horses, following the old strict precepts, failed to find the colon, but found the upper part of the small intestines, and so had a most alarming form of fistula result, which tended to hasten their patients over to the majority more quickly than otherwise. This operation became useful only when the bowel was attacked from in front. The greatest drawback to lumbar colostomy was that the patients could not control their movements. This was obviated when the artificial anus was made in front. Regarding the various methods he wished to state, from his own experience and that of his colleagues, that there was no one operation invented that would obviate all the drawbacks of an artificial anus, such as leakage, etc. He believed that the old operation, the old Maydl procedure, gave just as admirable results in that the patients could control their bowels. These muscular methods he did not think were always successful; certain conditions arose which each surgeon must contend with, and which were peculiar to each individual case. He called attention to the enormous difference in the tonus of muscles in various individuals—a strong muscular man had a tonus of muscles different from that in a woman who had borne ten or fifteen children. All this showed that the operation was not yet what it ought to be. On the other hand, he stated that old operations had given good results. Why any operation had not been successful we have learned to explain in some cases, but not in all. For instance, in some cases there was found an extremely long mesocolon; sometimes there was found a short mesocolon, and then the operator was in a quandary as to further procedure. The status of the colon was very important. Prolapse could be prevented by withdrawing as much as possible of the bowel, making a tense mesocolon, and then sacrificing to prevent eversion of the mucous membrane. Most disagreeable effects were produced by the irritation of the skin, which was caused by the irritable qualities of the acidulated contents of the intestines. If the intestinal contents were neither alkaline nor neutral, but acid, an eczema would be produced which was difficult to control. The speaker emphasized the importance of intestinal hygiene, regulation of the diet to keep the fæces solid, often dosing with alkalies; he advised experimenting with the patient to learn what diet would keep the fæces solid in consistence. If these endeavors proved successful, large scybala would act as in the rectal pouch, and would produce an energetic contraction of the bowel, and the whole mass would be expelled.

Methods of Closure.—Very frequently and very fortunately, surgeons were called upon to close an artificial anus after its purpose had been fulfilled. This was one of the most agreeable duties a surgeon had to perform. The two methods were (1) extra-peritoneally; (2) intra-peritoneally. The extra-peritoneal operation was less risky, yet a great drawback was the fact that it so often resulted in ventral hernia. In women this was very disagreeable. He could hardly indorse the opinion expressed by the president that it was best to dissect away the colon from its adhesions, invert it, and then perform the radical operation for the cure of a ventral hernia.

DR. HOWARD LILIENTHAL said that an artificial anus could be made wind and water tight by the Gersuny method, in the sacral region. He was glad that Dr. Gerster had referred to the changed conditions regarding colostomy, and especially that he had brought it before this society. Many family physicians had old-fashioned ideas that the formation of an artificial anus meant an earlier grave; he did not believe that too much could be done to get rid of that idea. In spite of what Dr. Gerster had said regarding the closure of an artificial anus, he certainly believed that the danger was a pretty real one. He had had the hard luck to lose one patient in closing an artificial anus. The disease had been cured, but the patient died from his attempts to close the artificial anus. He believed that such a thing could happen, and it ought to make us more careful in advising colostomy in every case of cancer. He was not afraid of the operation, but he thought that patients should be made aware of the dangers in closing an opening of that nature. Regarding the extra-peritoneal method giving rise to subsequent hernia, it seemed to him that a subsequent operation could be performed safely. He felt that we were justified in attempting to close these openings extra-peritoneally.

DR. GEORGE WOOLSEY confessed that he still retained a certain dislike to the formation of an artificial anus belonging to that class called the permanent type. The reason had already been mentioned, that no operation had been invented that could control the evacuations. Personally he had never tried the operation reported to-night, but so far as the control of the movements went it seemed to him that it was better than Maydl's, which he had used. Regarding Dr. Abbe's question in reference to the vitality of the intestine brought out through the opening, he understood that it was the lower end of the gut that was necrotic in the third case of the president's, the upper end not being affected. He thought that, at the present time, intestinal anastomosis could in most cases take the place of the formation of an artificial anus in the small intestine. When an artificial anus was required simply as a temporary measure, he thought it might prove of value. If we had a perfect method of producing an artificial anus he thought all surgeons would admit the usefulness of the procedure to be very great.

DR. MARKOE said that the protrusion of the mucous membrane could be prevented by drawing down the upper loop; in that way there was no question that the discharge from the upper into the lower loop could be avoided. At the present time he had two patients in whom, by slight attention to the food and by a properly fitting pad, this was prevented. In the presence of a diarrhœa there was no remedy for this great drawback. By attention to intestinal hygiene he thought we could get a fair control. The relief of pain and of a certain amount of sepsis by the establishment of an artificial anus in cases of ulcers, carcinomas, etc., he thought was very marked.

DR. BREWER said that if the operation was done in the region of the cæcum there was less likely to be gangrene than if it was done in the descending colon; the anastomosis there was freer.

DR. ROBERT F. WEIR closed the discussion. He believed the determining question was the possibility of gangrene in that portion given back into the abdominal cavity.

Medical Items.

A Trichobezoar (hair tumor) weighing 160 gm. in a dry state, and removed by laparotomy from a twelve-year-old girl, was demonstrated by Schopf on October 27, 1899, at the Gesellschaft der Aerzte of Vienna. The girl, from her fifth year on, had been in the habit of biting at her hair. About a year before the time of operation the patient began to vomit and to have pains in the stomach; a tumor appeared in the region of the stomach, and was diagnosed as a floating kidney. A long process of the hair tumor extended into the duodenum. With the operation all disagreeable symptoms disappeared. According to Schopf bezoars are common in animals (horses, goats, cattle, swine, etc.), but only sixteen cases have thus far been described in man, and of these seven have been cured by operation. — *Wiener med. Blätter*, No. 44, 1899.

Traumatic Aneurism of the Carotid Artery Caused by a Sewing Needle.—Douty (*Lancet*, December 9, 1899, p. 1584) reports the case of a man, sixty-two years old, thin but healthy in appearance, without a history of syphilis or of other previous illness of importance, who three weeks before coming under observation began to complain of soreness of the throat, with difficulty and pain in swallowing. Nineteen days later a lump appeared on the right side of the neck, and on the following day the patient began to spit blood. This latter symptom had persisted for two days. The blood was bright red in color, and frothy in character. It was generally expectorated in small quantities, although it was stated that on two occasions the patient had been nearly choked by a sudden rush of a pint or more of blood. On examination a pulsating swelling was found on the right side of the neck reaching from the angle of the jaw to the clavicle. A thrill and a loud bruit synchronous with the systole of the heart were present over the swelling. The area of cardiac dulness was normal. On auscultation nothing abnormal could be detected in the heart-sounds except that the aortic second sound was accentuated. There was no appreciable difference between the radial pulses on the two sides, but the right temporal pulse was markedly smaller than the left, and also delayed in time. The right pupil was contracted. Digital examination of the pharynx revealed an ulcer behind and below the epiglottis on the right side, from which point the blood appeared to come. The patient was operated upon within a few hours after coming under observation. The swelling extended so far down that it was thought necessary to tie the innominate artery. This vessel was explored, but the proximal part of the carotid being found healthy, this vessel was tied with two silk ligatures about a quarter of an inch from the bifurcation, and the pulsation of the tumor ceased absolutely. There was much restlessness after the operation, but this was controlled by hypodermic injections of gr. $\frac{1}{6}$ of morphine. On two occasions during the following day there was marked left unilateral sweating of the face and head, each lasting for about an hour. A small quantity of blood was expectorated. Subsequently the patient again became restless and the pulse weak, and death occurred suddenly. On opening the incision after death the artery was found to be securely tied by double ligatures, below which there was no aneurismal dilatation. The first part of the aortic arch appeared to be dilated, but when opened afterward nothing abnormal was to be seen, and its circumference was found to be normal. The common carotid was lost in a mass that was copiously suffused with blood, so that it was impossible to dissect out the various structures. The carotid artery, however, did not open into anything like an aneurismal sac. In the process of dissection the mass broke down, and much soft coagulum appeared. The tumor-like mass was formed below the angle of the jaw or on a level with the thyroid cartilage. On careful dissection it was found that the spine was not affected—*i.e.*, not eroded, etc.—and that the bleeding had extended behind the pharynx and the œsophagus, forming a small tumor-like mass on the left, on a level with the cricoid cartilage. On opening the carotid and tracing it upward, no aneurismal dilatation whatever was found, but on a level with the cricoid cartilage there was an eroded opening through which blood had passed into the parts around, so as to produce the hemorrhagic tumor-like mass. Just outside, *i.e.*, to the right of the carotid artery, on a level with the eroded opening, a sewing-needle was found, point downward and blackened. On opening the pharynx and the œsophagus, on a level with the upper border of the cricoid cartilage, an ulcer was found opening into a cavity as large as a hazelnut. This cavity was continuous with the hemorrhagic mass on the left and on the right. It was, therefore, assumed that the needle had caused the ulcer and that it had passed through the œsophageal and pharyngeal walls, and pierced the carotid artery, producing a traumatic aneurism. There was neither atheroma nor granular kidney. There was much œdema of the veil of the palate and the posterior wall of the pharynx, and also of the larynx. There was, however, no evidence of paralysis of the vocal bands, although the right band was œdematous. Lungs, heart, and brain were normal. It was learned that the patient had been a beer-drinker, and that he drank large quantities. A week before his symptoms had begun, he had, when with friends, drunk a very large quantity, and more than was good for him. It is probable that while semi-intoxicated he swallowed the needle, which became impacted in the pharynx, working its way subsequently into the carotid artery.

Deadly Drugs are manufactured on a large scale in Baltimore, and a recent publication of that city gives many interesting facts connected with their production and the care necessary on the part of the workmen employed. Hydrocyanic acid is produced in air-tight retorts and receivers to obviate the danger from inhaling the fumes, which even in minute quantities are deadly. While the compounds of copper and sulphuric acid are considered dangerous, the manufacture of nitric acid seems to be especially dreaded, because of its volatility. The story is told of the accidental breakage of a carboy of the acid, setting fire to some sawdust and then to a room in which many men were at work. Four workmen who volunteered to put out the fire to save the entire works succeeded in their efforts and were apparently unaffected by the fumes, until four hours later, when each became ill with distress in the chest, and in less than an hour all four were dead.

X-Rays in Pregnancy.—*The Lancet*, in its annual review of the Annus Medicus in its issue of December 30th, discourses as follows upon the above subject: "Very little progress appears to have been made in the use of the *x*-rays in cases of pregnancy. Professor Varnier, writing in April last, announced that while he had been able to obtain fairly good photographs of the child's head and its relation to the pelvis, he had not so far been able to obtain complete photographs of the whole fœtal skeleton in any one case. It is possible to obtain a good idea from an *x*-ray photograph of the volume, position, degree of flexion, and amount of engagement of the head, but so far no attempts have been successful with the mother in the dorsal position in obtaining a complete view of the whole fœtal skeleton in utero. He believes the difficulty to lie in the fact that the pelvic and abdominal parts of the uterus lie in different planes, and, further, in the extreme thickness of the intervening maternal tissues—namely, the back muscles and the spinal column.

Modesty is a characteristic of physicians as a class, just as it is of all the truly great. Recent literature has shown one or two lapses. An Australian physician, for example, has described what he thinks to be a new affection, and has named it after himself in large type, instead of waiting for others to pay him the compliment.

Health Reports.—The following cases of smallpox, yellow fever, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 14, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alabama, Huntsville	April 4th	19	
Mobile	April 1st to 7th	11	
Colorado, Arapahoe Co.	March 28th	4	
El Paso Co.	March 28th	1	
Las Animas Co	March 28th	1	
Rio Grande Co	March 28th	1	1
Weld Co	March 28th	3	
District of Columbia, Washington	April 1st to 7th	6

BOTTINI'S OPERATION FOR THE CURE OF PROSTATIC HYPERTROPHY.[1]

By WILLY MEYER, M.D.,

NEW YORK,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

Mr. President and Gentlemen: Bottini's operation for the cure of prostatic hypertrophy has come to stay. The experience of the originator of the method, covering a period of more than twenty years, and of many operators all over the world during the last three years, has proven the value of the procedure beyond the show of a doubt. If properly carried out in a suitable case, Bottini's operation *can* cure the patient afflicted with prostatic hypertrophy. It, therefore, clearly belongs to the class of radical procedures that have so far been devised for the treatment of this trouble. And it can cure such a patient in a comparatively simple way at a stage of the disease when even the most enthusiastic advocates of prostatectomy would not propose the operation, and the patient surely would refuse to submit to it; it can cure when prostatectomy might be impossible on account of, for instance, the too great softness of the gland, or of the too far advanced age of the patient. What remains to be done is to give Bottini's operation its proper place among the various radical operations for the relief of prostatic enlargement, to determine its proper indication.

Certainly this operation must not be done indiscriminately. The cases must be carefully selected, the same as has to be done for prostatectomy. Nor do I believe that the latter procedure will ever be entirely supplanted by Bottini's operation. But we shall have to learn which class of prostatic enlargement will be suitable for the former and which for the latter method of operation. It will, no doubt, take us a good while to determine this definitely, since nearly every case of prostatic enlargement in the advanced stage has its peculiarities, and is different in some respect from every other. A much greater series of cases will have to be operated upon, carefully observed, collected, and unbiassedly published by each individual operator, before we shall learn to decide this question of indication. I personally am inclined to believe, however, that the result of such investigation, based, not on "enthusiasm" as is so often claimed by the opponents of Bottini's operation, but on cold facts, will tend to lessen the indication for prostatectomy and establish the necessity of early operation for the disease in question according to Bottini's method.

As regards the results so far obtained with Bottini's operation, they have demonstrated: (1) that the urinary troubles of prostatics are not dependent upon a weakness of the muscles of the bladder, due to arteriosclerosis (Guyon and Lannois' theory), but are the direct result of a true mechanical obstruction to the normal outflow of the urine at the neck of the bladder, viz., the enlarged prostate gland; (2) that we are able to overcome this mechanical obstruction in a comparatively simple manner, namely, by the multiple division of the swollen gland with the galvano-caustic knife, which latter is part of a modern and reliable instrument; (3) that we can generally accomplish this without any additional operation on the cords, testicles, or bladder; (4) that we have every reason to expect that, if the desired result of the operation be once thoroughly obtained, the cure will in most cases be a permanent one.

In view of these facts it becomes the duty of every one who takes an interest in the further development of this procedure to give a résumé of his work from time to time, and make known the conclusions he draws from his experience. A proper comparison and study of these conclusions of the various operators will call forth suggestions as to the still further improvement of the technique of this delicate operation, and will place the indication for its performance on a firmer basis.

This is all the more important as there still are colleagues who not only condemn the operation as such, but deny that it does or ever will deserve the designation "radical." One of them recently claimed[1] that a cure could not be obtained by the operation, because the division of the prostate gland with the galvano-caustic knife could never effect "the restoration approximately to its normal position of the attachment of the vesical muscle to the prostate." This he considers one of the essential points in curing prostatic hypertrophy by direct interference. Of course, the argument is advanced on purely theoretical reasoning, according to the doctor's own statement. The author of the dictum as reported in the Medical Record "had done the operation but once. In spite of all efforts, the result was most unsatisfactory. He had seen several cases which had been operated upon by this [Bottini's] method by well-known surgeons, and in all of these the later results of this operation had been unsatisfactory. The operation did not promise to accomplish sufficient drainage to the bladder. The best that could be said for Bottini's operation was, that it caused temporary amelioration in the symptoms of retention. He desired to protest against the views which were being so freely expressed, by men whose opinion was entitled to respect, in favor of this operation; too much had been claimed for it. . . . It was a good thing to be progressive and to try new things, but it was most unfortunate to permit our enthusiasm to interfere with our scientific judgment."[2]

How a medical man can make so sweeping a statement in face of the entirely different experience we find published by surgeons all over the world, I cannot understand. He either did not follow the recent literature on this subject, or he refuses to accept as true the statements made by some of the most conscientious and unbiassed observers. However, with purely theoretical reasoning and sweeping statements, one can no longer nullify such absolutely positive and favorable results as have been achieved with Bottini's operation here and abroad. That time is past.

---

[1] Read by invitation before the Medical and Library Association of Detroit, February 26, 1900.

[1] Report in Medical Record, December 30, 1899.

[2] The doctor's part in the discussion was read from a typewritten manuscript and then handed to the gentleman representing the Medical Record at the meeting. The report, as printed, is therefore authentic.

In view of the fact, however, that there still are such disbelievers among us, I deemed it my duty again to come forward and tell what I have learned regarding this operation in the course of my experience, which now covers thirty operations on twenty-four patients. Hence it was with a great deal of pleasure, indeed, Mr. President and gentlemen, that I accepted your kind invitation to come to Detroit and address you on a subject of my own choice. I really could find no better one than that now before us. I dare say it is superfluous for me to tell you how highly I appreciate your courtesy, which enables me to lecture here to-night before so distinguished a body of men. I know that the interest of the profession in the West for this fascinating procedure has been great from the start, that is, since the time when Freudenberg of Berlin revived it, and the first Bottini operations on this side of the ocean were done in New York in the fall of 1897.

Bottini's operation, at first glance, appears to be a very simple interference indeed; and while this is true of its immediate technique, it is by no means so with regard to many of its details. The point in this operation, the same as in every other, is not so much to do it, but to do it properly. And this certainly requires a great deal of personal experience, especially yet at present, when the patients afflicted with a hypertrophied prostate do not apply, as a rule, to the surgeon for relief until the disease has reached a very advanced stage. If we extirpate a vesical growth, or if we crush and evacuate a stone from the bladder, we know more or less what we have accomplished. We see the result of our work before us. Barring unforeseen complications, we are able to predict, with a reasonable amount of certainty, the future course of the disease. Not so with Bottini's operation. It will be a long time, I think, before we shall be able to state a definite prognosis in a given case immediately after the operation has been performed. The patient as well as the doctor must await further developments. It is just this uncertainty, however, that makes the after-treatment of the operation so interesting, and that, if the outcome be successful, gives the surgeon an amount of satisfaction that he can rarely hope to find in any other branch of operative surgery.

In order to unroll before your eyes a proper picture as to the present status in the evolution of Bottini's operation, it appears to me best to review, as briefly as possible, the different phases of the technique of the operation as they present themselves to us during its performance. This will enable us to determine, to some extent at least, how we can hope to avoid complications during the after-treatment, how we can hope to bring to the patient not only partial and temporary, but total and permanent relief, and that by means of one single operation.

I. Preparation of the Patient.—The patient is prepared in general the same as he is for any other surgical procedure. On the day prior to operation the bowels are thoroughly emptied, and the whole body is cleansed in a lukewarm bath. Shaving is unnecessary, as is also fasting. Local anæsthesia suffices for the operation. Fifteen grains of quinine are given on the night preceding the operation, eight more about one hour before the latter is done. As Nitze has found in his intravesical mode of removing benign tumors of the bladder with his operating cystoscope, internal administration of quinine prior to operation is the best prophylactic against the appearance of the so-called urethral fever. If one wants to be especially careful, the quinine is administered a number of days in advance of the operation, best, it seems, in connection with two to three grains of methyl blue (Freudenberg). See below under "urethral fever."

II. Instruments.—As stated in my paper read before the New York Academy of Medicine, November 3, 1898,[1] Bottini's incisor, as modified by Freudenberg, is now manufactured in New York, in a most satisfactory way. In my last twelve cases I have made use of this incisor and have not had a single complaint to make of it. Once only within the last year did it become necessary to have the incisor repaired, the knife not sliding in its groove with sufficient ease. For safety's sake, however, I invariably have two instruments on hand for every one of my operations; for it could well happen that the operator or his assistant might drop the instrument, or injure a part of it, etc., and thus the operation would be rendered impossible for that time. I certainly have derived great comfort from the sense of security afforded by the presence of a second instrument, the proper working of which I had also previously tested, to fall back on in case of an accident to the first. The incisor I use—which is a copy of that made by Kiss, of Berlin—can be easily unscrewed and sterilized in boiling water.[2]

A very important point is the proper heating of the knife. Recently I was informed that a colleague in Boston had had trouble with the incisor made in New York. Great difficulty had been experienced in extracting it, and when finally removed from the urethra it was seen that the blade had bent sideways. I fancy that in this instance too much current had been applied. It can be readily understood that if we overheat the knife, a slight unintended twist of the shaft, the handle of which rests in the left hand of the operator, or a sudden move on the part of the patient, may turn the knife sideways. On its return trip through the prostate gland it will then not re-enter the groove at the beak of the female part. The best means of heating the knife is certainly the current supplied by a central station. With the help of an alternator and rheostat we have full control of it and an inexhaustible, steady supply. Unfortunately, it is not everywhere at hand. Hence we need a storage battery. The one with an amperemeter, as recently brought out by me—best answers the purpose, I think.[3] It gives 50 amperes, and if properly charged will furnish sufficient current for the work. It must be well taken care of, however. a weakness which it shares with all other batteries. Special directions are sent out with each battery. If they are properly followed, many repairs and consequent annoyances to the operator will be avoided. To guard against possible disappointment, it is advisable to recharge the battery the day previous to the operation. When using two 50-candle-power lamps it will take ten hours to charge the battery; five hours when two 100-candle-power lamps are employed. When fully charged, the battery will store sufficient electricity to do three successive operations, each lasting about ten minutes; but if they are not done on the same day, recharging is advisable, for the current steadily diminishes during non-use.

To demonstrate the importance of personally supervising the charging of the battery in cases in which the street current is not available for doing the operation, I will relate the following instance: Recently a colleague who, with me, believes in the efficiency of Bottini's operation, told me that the storage battery, as designed by me, had given out in the midst of the operation, and therefore could not be looked upon as a reliable supply. Upon my query whether he had charged the battery himself, he answered that it had been sent to him with the statement that it was properly charged. On further inquiry I learned that the company which had furnished the battery was not in a position to charge batteries, for the reason that it was not connected with the street current, and that it therefore sent all batteries entrusted to it for charging to another concern. I am sure my friend would have been saved the annoyance above mentioned, had he personally supervised the charging of the battery. The only disadvantage of this battery is its weight. It is heavy. Experience has shown, however, that cells of smaller size cannot be trusted for this particular kind of work.

[1] "Personal Experience with Bottini's Operation in the Radical Treatment of Hypertrophy of the Prostate." MEDICAL RECORD, January 14, 1899.

[2] *Cf.* Author: "Bottini's Galvano-Caustic Radical Treatment for Hypertrophy of the Prostate." MEDICAL RECORD, March 5, 1898, p. 327.

[3] The addition of an amperemeter to the battery used for Bottini's operation, we owe to Freudenberg.

III. Operation.—Bottini's operation is certainly one of detail. "The oftener I applied the galvano-caustic incision," says Bottini,[1] "the more I became convinced that the technique requires adroitness and care in order to avoid annoying surprises. To be successful with the operation is not mere chance, but the result of careful study and conscientious performance." I therefore do not hesitate to describe to you minutely all the various steps to be observed in the course of the procedure, even at the risk of overtaxing your patience.

I personally carry the operation out in the following manner: The surgeon, after proper sterilization of his hands, should stand on the right side of his patient, who is placed on a table and covered below and above the pubes with sterilized sheets or towels. The glans and prepuce are thoroughly cleansed with soap and water, bichloride solution, and alcohol, the same as is customary in our daily operative work. The battery is placed on a table to the left of the patient, so that it is always in full view of the operator. A soft-rubber catheter which has been boiled for three to five minutes is taken from the bowl of sterilized water and handed to the surgeon, its tip being lubricated with boiled glycerin or sterilized paraffin. It is first introduced down to the cut-off muscle, and the anterior urethra is then irrigated with a two-per-cent. sterilized boric-acid solution. After that the catheter is pushed on into the bladder. If the soft-rubber catheter cannot successfully overcome the obstruction at the neck of the bladder, a Mercier's gum-elastic—which I keep disinfected in a five-per-cent. solution of formalin with glycerin—must be used. Then the bladder is thoroughly irrigated with the same two-per-cent. sterilized boric-acid solution, until the water returns clear. As soon as the latter has been accomplished, 50 c.c. of a three-per-cent. sterilized boiled eucaine-B solution is drawn into a hand syringe; the catheter is pulled out so far that its eye still rests within the posterior urethra, and the solution is slowly injected. This will produce local anæsthesia of the parts to be operated upon.[2] The catheter is pushed back into the bladder and its outer end closed with a stopper. During the following five minutes—the time required to produce sufficient and proper local anæsthesia—the operator will do wisely to test once more the proper working of the incisor, which has meanwhile been taken apart and boiled. Bottini himself advises to test the heat of the knife on a piece of moist gauze or potato. I must confess that I no longer do this, but trust in the reliability of the instrument and the proper charging of the storage battery which I personally superintend. If the current turns the knife to white heat, I am satisfied. This generally occurs when the needle of the amperemeter in my battery points to 45–48. A properly instructed attendant takes charge of the battery and, later on, turns the rheostat till 48 or 50 is reached, according to the orders of the operator. The cable attachment is now pulled off the instrument, and a long and small rubber tube, previously boiled, is slipped over the two metal tubes which are attached to the handle of the incisor, for the purpose of supplying and carrying off the ice-water used to cool off the instrument when at work. Thus prepared, the incisor is placed on an aseptic towel.

After the expiration of the five minutes allowed for the local anæsthetization, the eucaine solution is withdrawn, and 150 c.c. of a sterilized boric-acid solution introduced. The catheter is pulled out. Then the patient's pelvis is placed on a hard pillow some twelve inches high, so that the upper part of his body is tilted slightly downward.

He spreads his legs, between which a pus basin is placed on the table. With a small sterile glass syringe the anterior urethra is now once more washed out with sterilized boric-acid solution and then filled with three-per-cent. eucaine solution. While the fingers of the left hand compress the urethra near the external meatus, those of the right hand gently massage for a while the urethra toward the bladder. By doing this a part of the eucaine solution is pressed into the posterior urethra. This still further insures complete local anæsthesia of the latter. After the remaining part of the solution has run out of the meatus, a syringeful of sterilized paraffin is slowly injected into the anterior urethra, the meatus being compressed. The nurse then hands the incisor to the surgeon for introduction into the bladder. In the majority of cases the handle must be deeply pressed down before the beak slips into the viscus. Cases in which the instrument cannot be introduced at all will be a rare occurrence, I think. In one only of my twenty-four cases did I find difficulty, but I succeeded in my third attempt.[1] As soon as the instrument has entered the bladder, it is turned around, and the glass nozzle of the fountain syringe which contains the ice-water is attached to the long rubber tube previously fastened to the handle; the short tube is made to enter the pus basin between the legs of the patient. Now the cable attachment is slipped over the upper end of the instrument, and the prostate well hooked with the beak of the incisor exactly in the median line. This is one of the most essential parts of the operation. At this stage the right forefinger (covered with a finger cot) of the operator should be pushed into the rectum in order to control the place of the tip of the beak within the bladder and properly gauge its distance from the anus. In patients with a very much enlarged gland, a short forefinger will never succeed in feeling the tip of the beak. For such instances it will be well to have an assistant at hand on whom nature has bestowed a forefinger long enough to enable him to reach up four inches and more above the anus, as I have found it necessary in two cases. Having measured the distance of the beak from the anus, the operator must make up his mind how long the incisions should be made in the given case. Now the rheostat is turned, so that the needle points to 45 amperes. The screw of the cable-attachment, which makes and breaks the current, is turned to the right and tightened. We wait about fifteen seconds—the time required for properly heating the knife. The real operation may now be started. I now generally make three cuts, one in the median line directly posteriorly and one through each lateral lobe. The posterior cut is, of course, the most important one. It is made first. As stated in my former paper, the incisions are made very slowly, by turning the outside screw as if the knife had to overcome a very great obstacle, with 45 amperes. For the return trip 49-50 amperes are turned on; this, too, is made at no greater speed than the first. The lateral cuts I make at an angle of from 45° to 90,° and I must confess that I have no definite rules yet that guide me in determining the exact angle. So far I have based my decision in this respect on the previous cystoscopic examination and on rectal palpation; that is to say, the larger the lobe the more acute the angle. The anterior cut I have given up entirely since it caused me the loss of a patient (see below, Case XVII.). While the incisions are being made the assistant now and then auscultates the suprapubic region to make sure of the sizzling noise produced by the cauterization. However, the odor of burnt flesh, escaping from the meatus, and especially the needle of the amperemeter give us assurance that the work is being properly done. The operation performed this way takes me generally about ten minutes, counting from the moment the current has been turned on until the third incision through the gland has been finished. During this time I never turn off the current, but only reduce its strength to 45 amperes after each return trip of the platinum knife. The three cuts having been properly made, the current is turned off and the cable detached from the instrument; the latter is turned 180° and slowly withdrawn. During this procedure I continue to let the current of ice-water pass through the instrument. A reintroduction of the catheter for final irrigation I deem unnecessary. The patient, after being cleansed, is brought to bed.

---

[1] Langenbeck's Archiv, vol. liv., p. 118.

[2] For the last four weeks I am trying a one-per-cent. sterilized watery solution of chloretone, for producing the desired local anæsthesia, with quite satisfactory results so far.

[1] Freudenberg had an interesting experience in this respect in a patient sixty-seven years of age, who had had complete retention for the last two years. He was absolutely unable to enter the bladder with any stiff instrument; cystoscope, stone searcher, sounds, as well as Bottini's incisor, were all unsuccessfully tried. The operation had to be abandoned for that day. On the following days sounds of increasing size could be introduced; three days after the first attempt the introduction of the incisor succeeded, though with some difficulty. Bottini's operation was done, and the patient was cured.

IV. After-Treatment.—In my former cases I generally insisted upon the patient's attempting to pass some water immediately after the operation, but found that very few only were able to discharge a few drops under pain, and I therefore no longer make this request; although I am sure that in a number of cases the occasionally following urethral fever would be avoided if the patients could, immediately after operation, clean the urethra with part of the fluid retained in their bladder. I have also given up attempts at introducing the catheter into the bladder as a routine practice directly after the operation, with the view of leaving it in place, except in cases with a very pronounced vesical catarrh, and in which catheterization had always been difficult. I now prefer to await further developments, but must confess that I am always relieved to learn that the patient has begun to void urine voluntarily within the first hours after operation. If, on the other hand, retention sets in, the reactive swelling of the gland in advanced cases may be so tremendous as to tax to the utmost our capability of emptying the viscus (see below, Case XX.). If the patient begins voluntarily to urinate, the after-treatment is comparatively simple. "Hands off" is the watchword as far as instrumental interference is concerned. The probably following painful spasms at the neck of the bladder are overcome by morphine and suppositories of opium and belladonna. Salol, urotropin, and strychnine (as stated in my former article) constitute the drugs used for internal medication.

Some patients, while they are able to pass some water after the operation, are subject to such great and constantly recurring pain during and after each act of micturition, day and night, that they are soon worn out. In such instances, whatever we may employ, anodynes, sitz-baths, or permanent catheter, is of no avail. With the withdrawal of the latter—even after six or seven days of continued drainage—the pain reappears, and early repetition of the operation is the only alternative left to these sufferers. This brings relief, as I have observed in two instances (see Cases VII. and XX.). In cases in which absolute retention follows, and the introduction of the catheter is not difficult, I should prefer the use of the latter at regular intervals of six to eight hours, rather than to leave it in place permanently. The latter, no doubt, produces funiculitis and epididymitis oftener and more easily than frequent catheterization.

In instances in which a chill sets in, the surgeon must be careful to interpret its cause correctly. The chill may simply mean urethral fever of a few hours' duration; it may mean the beginning of a prolonged feverish attack, or of a more profound sepsis or pyæmia; or it may be the first warning of a perforation of the urethra from within with the galvano-caustic knife. Careful local and general examination will soon enable us to make a distinct differential diagnosis. The first three occurrences would have to be treated on general principles. Perforation of the urethra is promptly attended to by a perineal incision under eucaine, followed by drainage. If perforation has occurred, one can rest assured that the posterior incision has been efficient (!).

Inflammation of the cavum Retzii will not happen if we omit the anterior incision.

The length of time that I keep patients under my immediate supervision averages three weeks. While this may seem, and is, longer than necessary in some instances, it is not safe to let patients go any earlier, for the reason that hemorrhages may set in as late as twelve to twenty days after operation, the time when the eschars are cast off from the gland. If patients walk around, these hemorrhages may become more serious. They are generally easily controlled by rest, if more severe by the permanent catheter. In a few instances they have required suprapubic cystotomy and packing with gauze in the hands of others.

In favorable cases the quantity of urine discharged at each micturition will with lessening frequency gradually and continually increase until the normal amount is reached, in say two or three weeks, sometimes earlier.

I should now like to discuss a few important questions in connection with the operation, regarding a number of which differences of opinion still exist.

Should Cystoscopy Invariably Precede Bottini's Operation?—There can be no doubt that cystoscopy is of utmost importance, not only in establishing the diagnosis of prostatic hypertrophy, but also in determining the configuration of the gland. In cases in which the enlarged prostate is not palpable per rectum, and, according to Albarran and Motz, this is so in almost twenty-eight per cent. of all the cases—the cystoscope alone can establish the exact diagnosis. We see the pathognomonic groove at the internal urethral fold; on turning the prism posteriorly down to the fundus, we see the body of the gland often bulging into the bladder; on turning it to the sides, we recognize distinctly the enlarged lateral lobes, though not in full illumination. We are, furthermore, enabled to determine the absence or presence of a median lobe. And even if all these symptoms should, in exceptional cases, be but imperfectly developed, the finding of a trabecular bladder in the absence of a urethral stricture would still settle the diagnosis beyond dispute. Then, too, the cystoscope enables us to diagnosticate the presence of a vesical calculus which had not been suspected before, on account of its symptoms having been masked by those of the prostatic enlargement. Only very recently did I thus detect a stone in the bladder of a patient who had not had one of the clinical symptoms generally attributed to vesical stone.

Yet, notwithstanding the great benefit that may be derived from cystoscopy in obscure cases, it may become harmful in some instances, as for example in prostatics with chronic sepsis. Here cystoscopy, the same as any other intravesical instrumentation, may be followed by serious urethral fever. One should therefore well weigh the pros and cons in deciding whether this most desirable visual inspection should be added. I have grown particularly careful in this respect since I lost a case a few months ago as an indirect result of cystoscopy. The patient, a man of seventy-six years, who had been sent to me for Bottini's operation, was suffering with chronic cystitis and pyelo-nephritis. Cystoscopy was performed by me and followed by a protracted urethral fever to which he finally succumbed. I insisted upon the examination only because all symptoms pointed to the presence of a stone, so that it was necessary, under all circumstances, to resort to intravesical instrumentation of some kind in order to ascertain the correct diagnosis. The cystoscope proved the suspicion to be unfounded.

To sum up, I would therefore say: cystoscopy should precede Bottini's operation, provided there be no contraindication to its performance. What deserves to be especially emphasized, however, is, that in cases of doubt, *i.e.*, when the symptoms are misleading, and when all other means at our disposal for rendering the diagnosis could not be relied upon with absolute certainty, it is the cystoscope alone that can definitely clear up all doubt and enable us to establish the correct diagnosis even at an early stage of the disease.

Filling of the Bladder.—Shall we do the operation with the bladder empty, as Bottini at one time proposed, or shall we fill it with a fluid, or with air, or with carbonic acid gas?

1. Operation with the Bladder Empty: This procedure should be, and I think has been, dropped altogether. It is well known that by filling the bladder, at least to some extent, entrance to the same in prostatics per vias naturales is greatly facilitated. In the distended viscus the projecting hypertrophied rugæ of the detrusor muscle furthermore are smoothed out, and not so apt to be hooked by the tip of the incisor when gliding over the fundus of the bladder in order to hug the prostate. It was when doing the operation in this way that Freudenberg cut through a transversely running fold of the fundus of the bladder and lost his patient from acute sepsis.

2. Operation with the Bladder Filled with Sterilized Boric-acid Water: This is the procedure which, as stated above, I personally am still adhering to in my Bottini operations. What others claim to have experienced in their patients does not seem to me proven, viz., that the heating of the fluid immediately surrounding the galvano-caustic knife produces the scalding sensation. If the prostate is thoroughly hugged with the beak of the incisor, the knife must at once enter the prostatic tissue, and surely is surrounded by so very small an amount of fluid that I cannot understand how just the heating of this bit of fluid could be the principal source of the sometimes rather great pain to the patients. On questioning the latter regarding this point, I almost invariably received the answer that they did not mind the burning part of the operation, but that the pain produced by the compression of the prostate by far overshadowed all other sensations.

3. Operation with the Bladder Filled with Air: I personally should have no hesitancy about doing the operation with the bladder filled with air, were it not for the unfavorable results of the experiments made by Lewin and Goldschmidt, already referred to in my former articles.[1] I there stated that these two investigators had found that, under certain conditions, unknown to us, air may pass upward through the ureter into the pelvis of the kidney, and from there, by way of the branches of the renal vein, enter the inferior vena cava and the heart. Instant death is the result. I am aware of the fact that Dr. Bransford Lewis, of St. Louis, Mo., in his experiments,[2] has obtained results entirely at variance with the findings of the German investigators, and it was this report that impelled me to write direct to Professor Lewin, at Berlin, with a view to eliciting from him some data that might perhaps explain the apparent difference in their conclusions. Dr. Lewin, under date of June 29, 1899, sent me a most interesting answer, from which, with the author's permission, I quote as follows:

"The phenomenon of air ascending into the renal vein, etc., as well as the antiperistaltic transmission of liquid from the bladder into the pelvis of the kidney, does not occur in every animal. I have opened the abdomen of about two hundred animals in all, but have not succeeded in determining the conditions under which the experiment gives a positive result.

"I can say, however, almost with absolute certainty, that a constant pressure of air within the bladder, filling this viscus nearly to bursting, never produced the phenomenon in question. Whenever it appeared, it did so immediately after the injection of air, even when the bladder had been filled to a small extent only. It occurs, as it were, during the first moments when the air enters the bladder, sometimes also while injected air is allowed to escape again through the catheter; eventually, also, immediately after the second or third injection. Death is the absolutely certain consequence of the entrance of air into the venous system in this manner.

"I shall take opportunity, within the very near future, to demonstrate the aforesaid to Dr. Freudenberg" [who had then just stated, in a letter addressed to Dr. Lewis,[3] that he now also prefers to do his Bottini operations with air injection into the bladder, and who also, according to Professor Lewin, had interpellated him regarding the latter's entirely different findings from those of Lewis] "that he may learn from the same, what such experiments must teach, viz., *the possibility* of the occurrence of the phenomenon in question also in the human subject. More than that can, of course, not be claimed. The same conditions are extant here as obtain in the case of other dangerous operations. Hundreds of patients are unscientifically narcotized, the quality, the concentration, and dosis of the narcotic may not come up to the standard, yet, thanks to unknown circumstances, the patients do not die. But, in view of such occurrences, the conscientious physician will be mindful of the possibility of a fatal result."

With a view of obtaining personally further light on this important question, I have carefully studied the various original and other treatises of Professor Lewin regarding this subject.[4] The doctor's researches prove that the possibility of air entering the venous system by way of the renal vein does exist.

---

[2] MEDICAL RECORD, 1899, vol. lv., p. 425.

[3] MEDICAL RECORD, 1899, vol. lvi., p. 34.

[4] "Experimental Studies on the Relation between Bladder and Ureter," by Drs. L. Lewin and H. Goldschmidt. Berlin. klin. Wochenschrift, No. 32; paper read before the Berlin Med. Soc., July 12, 1893.—"Experiments on the Relation between Bladder, Ureter, and Renal Pelvis," by Drs. L. Lewin and H. Goldschmidt. Arch. f. pathologische Anatomie und Physiologie und klinische Medicin, vol. cxxxiv., i., Berlin, 1893.—"Absorption of Foreign Substances from the Bladder," published in the Arch.

In the face of these positive statements of Dr. Lewin, I believe I shall never agree to do Bottini's operation with the bladder filled with air. If sudden death should set in as a result of such filling, the conscientious doctor would have to confess that the lamentable outcome might have been avoided.

4. Operation with the Bladder Filled with Carbonic Acid Gas or Oxygen: As just stated, some colleagues claim that the operation is less painful and, perhaps, also more effective when done with the bladder filled with a gaseous instead of a fluid medium. It was on the strength of these assertions and of the unknown amount of risk attached to ballooning the bladder with air, that, upon the suggestion of Dr. A. Rose, of this city, I experimented with carbonic acid gas filling the viscus. The blood is, of course, capable of absorbing large quantities of carbonic acid gas as well as of oxygen. The small flasks filled with liquefied carbonic acid gas, make the ballooning of the bladder with this gas a very simple procedure. I have not yet done a Bottini operation with the bladder inflated in this way. The question which has first to be solved is the amount of expansion of the gas caused by the presence of the red- or white-hot platinum knife. This question does, of course, not concern us, if we would work with oxygen. However, the chemical production of this gas in smaller quantities, instead of making use of the large tanks sold in cities by every druggist, is less handy than the use of carbonic acid gas in the manner just mentioned; oxygen also does not possess that slight anæsthetizing property which various authors have claimed for carbonic acid gas. I shall not fail to report on the further evolution of this interesting question in the near future.

Length of Incisions.—The question as to the length of the incisions to be made through the gland undoubtedly constitutes the most important and, at the same time, the most difficult point in the technique of Bottini's operation.

a. In cases of *fibrous* prostates the length of the urethra measured from the external meatus to the internal sphincter muscle, that is to say, up to the spot where the water of a filled bladder begins to flow through a catheter which had been introduced, may serve as a reliable guide in estimating the proper length of the incisions to be made. Such a prostate can be but very little compressed. If we have found the length of the urethra, for instance, to be 29 cm., the incision may with propriety be made 8 cm. long, because we know that the normal urethra is on the average 21 cm. long. In other words, we make the incision correspond to the difference in length between the normal urethra and that in the given case.

It will be wise to control and possibly modify this decision reached before the operation according to the result of rectal examination after the prostate has been well hooked during the operation.

A useful clew in regard to the required length of the incision is furnished by rectal palpation, performed in the following manner: If an assistant (the proper length not only of whose forefinger, but also of each phalanx of the same, has been previously ascertained) inserts his finger into the rectum as soon as the prostate has been firmly hooked, and gropes for the tip of the instrument at the upper end of the gland, he can determine the exact distance of this tip from the anal ring. If he then again introduces his finger, measuring the distance of the lower end of the prostate from the sphincter muscle, and deducts the latter measurement from the former, we know the palpable length of the prostate per rectum. The length, thus found, can then be compared with the abnormal length of the urethra, previously ascertained. If, however, we now make the length of the incision exactly correspond to such rectal diameter of the prostate, we may find quite often that the incision has not been sufficiently long. I have noticed this in a number of instances, and have come to the conclusion that it will be best to make the incision about 1 to 1.25 cm. longer than the longitudinal diameter of the prostate found per rectum. That is to say, if the tip of the beak was 8 cm. distant from the sphincter muscle and the lower end of gland 4 cm. in diameter, we should not make the incision 4 cm., but 5 to 5.25 cm. long.

b. All these points are entirely different, however, in the other far more frequent class of prostatic enlargement, namely, that in which *the glandular elements preponderate*, and in which, consequently, the organ can be compressed. Here the simple means of measuring the length of the urethra is of little avail, for it is obvious that the length of the urethra found before operation will be entirely different after the beak of the incisor has hugged the compressible gland. This shows clearly that in this class of cases the length of the cut to be made cannot be determined beforehand, unless we should, as a preliminary measure, ascertain to what extent the prostate may be compressed. Such a procedure, however, generally is inadvisable, inasmuch as it might be followed by very serious symptoms, so much so that Bottini's operation, the one interference that is likely to bring relief to the patient, might be rendered impossible. This question, how long must and dare we cut in the given case, must therefore, in the majority of our Bottini operations, be reached during the operative work. Some of the unforeseen occurrences that may then baffle the operator are, that a large median lobe may be turned back and thus increase the length of the urethra by almost an inch; or it may happen that the gland, which appeared quite large on rectal palpation, is so much compressed by the hugging beak that its diameter shrinks to almost *nil*, and the surgeon will ask himself whether his diagnosis, clearly established by all the exact clinical methods at his disposal, was correct, and whether there ever was an enlarged prostate.

That the occurrences here mentioned may often put the operator into a most annoying position, will be readily admitted. For if, in the case of a fibrous prostate with lengthened urethra, he should exhaust the full length which the ordinary incisor permits of cutting, namely, 4 cm., the incision may easily be too short and never properly divide the obstruction down into the prostatic urethra; an experience which I have had in a few cases. Or if in a soft, compressible gland he should make an incision of only 2.5 to 3 cm. in length, he may at once do a real internal posterior urethrotomy and perforate the urethra, an accident that happened to me in two instances. When operating on a patient with a very large prostate, and correspondingly lengthened urethra, I therefore now always make use of an instrument which allows of making incisions as long as 8 cm. This I have had made specially for such cases, in February, 1889.

I should strongly advise to make use of the incisor that permits of the long cut, (1) whenever the prostatic enlargement is very pronounced, so that the upper border of the gland cannot be reached on palpation per rectum, and particularly if the organ be of the fibrous variety; (2) whenever there is a median lobe of some size present; (3) whenever the length of the urethra has been found to be materially beyond normal.

---

f. experimentelle Pathologie und Pharmacologie, vol. xxxvii., 1896, by Professor Lewin.—"The Passage of Hard Substances from the Bladder into the Kidneys and Remote Organs of the Human System," also "The Entrance of Air from the Bladder into the Heart and the Path it Follows," by L. Lewin, with microscopical contributions by Dr. Lommen. Arch. f. Experimentelle Pathologie und Pharmacologie, vol. xl., 1897.

In patients with a very soft and compressible prostate, on the other hand, I now make incisions not longer than 1 to 2 cm. I do not, however, in such cases omit to explain to the patient or his relatives why I had to make short cuts: that, in case of partial relief only being obtained by the operation, a possible repetition might become necessary, and that this would surely be preferable to perforating the urethra in our endeavors to overcome the obstruction by a single operation.

Number and Direction of Incisions.—As a rule three incisions should be made at every operation. Of these, as I have repeatedly stated in the course of this paper, the posterior one is the most important, since upon it principally depends the success of the operation. If properly carried out it must and should lower the prostatic urethra to the fundus of the bladder. In very much enlarged glands, and especially in the fibrous variety, I shall in future make it a point, when doing the posterior incision, to have the knife plough through the same groove twice in succession. Such a procedure is not likely to be followed by complications; at the same time it is sure to enhance the probabilities of obtaining the desired result.

The question of definitely determining the proper angle at which the lateral lobes had best be divided has not yet been solved. Practical experience has shown, however, that it is not of very great importance. As stated before, I am guided by rectal palpation and cystoscopic examination, that is to say, if these show considerable difference to exist between the size of the lobes, I cut through the larger lobe at a smaller angle than through the other, in order to obliterate more thoroughly the communicating blood-vessels. For it is evident that the closer together the cuts, the more effective will be the destruction and obliteration; in other words, local atrophy must be the result of such close division.

The anterior incision I have found to be of real danger. It should therefore be dropped; or at least made only in cases in which the result after the first and second operation is incomplete, and in which cystoscopy plainly shows the mechanical cause to be situated in the anterior aspect of the internal urethral fold. Freudenberg has recently published a very striking illustration of this condition.[1]

Depth of Incisions.—In order to insure the proper depth of the incisions the following three factors should be carefully observed: (*a*) Position of the instrument during the operation; (*b*) the height of the knife and the proper heating of the same; (*c*) due slowness in making the incisions.

a. To bring the instrument into proper position for making the posterior incision, the outside handle has to be raised to such a point that one can feel the tip of the beak glide over the fundus of the bladder. In this position the prostate should be firmly hooked, after which the position of the instrument should not be changed again. Of course, care must be taken not to raise the handle too much, as by doing this the tip of the beak will be pressed down too far, and damage might result to the posterior wall of the bladder.

b. Freudenberg[2] considers 1.2 cm. ($\frac{7}{16}$ inch) the best average height of the knife. He has knives the heights of which vary between 0.8 and 1.5 cm. ($\frac{4}{16}$–$\frac{9}{16}$ inch) and bases his selection of the proper one on the cystoscopic examination and rectal palpation of the tip of the incisor, which had been put in position and turned posteriorly. Although this may perhaps be useful in some instances, I fear it complicates matters unnecessarily, and am, therefore, in favor of trying to operate with one and the same size of knife in every instance. Moreover, the knife when brought to white heat and drawn very deliberately over the field—if needs be, twice in succession—will produce such a far-reaching eschar that a difference in height of 3 mm. can be of no appreciable account, as Freudenberg himself also admits. It is, of course, of greatest importance that the knife be brought to white heat in its entire length, a point to which particular attention should be paid when testing the instrument as to its proper working. The height of the knife of the American instruments averages 1.2–1.5 cm.

Complications that Have so far Been Observed to Arise during Operation.—Complications that may arise during operation are:

1. Perforation of the Bladder: This may occur by hooking a transverse fold of the vesical wall with the tip of the beak of the instrument and perforating it by drawing through it the galvano-caustic knife when hugging the prostate. Filling the bladder with a liquid or gaseous medium will, I believe, avert this danger in every instance.

2. Perforation of the Urethra with the Electric Knife: This is a consequence of the incision having been made too long, an occurrence which, I fear, cannot be easily guarded against, if the work is to be done thoroughly, so as to avoid the necessity of a second interference. The complication, however, comes into question only in case of extremely soft prostates that are more compressible than the operator anticipated or could have imagined. I believe that in these instances the incision should not exceed two centimetres in length, and it will be well, as mentioned before, to prepare the patient or his relatives after the operation for the possibility of a repetition of it, in case the work just done should prove unsatisfactory or entirely unsuccessful. As much as I am in favor, in every other instance, of trying to get through with one operation, I believe that in these cases treatment in two or more sittings is to be preferred.

Other complications which might arise as a consequence of the instrumentarium as such, can, I am convinced, always be avoided. The accidents in question are bending of the knife, and giving-out of the battery. Bending of the knife will result from (*a*) overheating; (*b*) not steadying the instrument properly during operation; (*c*) an accidental movement on the part of the patient; (*d*) an assistant's finger pressing the prostate against the instrument.

By using the instrument manufactured here and keeping within the limits of 45–50 amperes, it seems to me that point *a* can always be avoided.

b. The surgeon should steady his instrument thoroughly during the operation, which rarely takes longer than ten minutes. The continuous cooling of the handle with ice-water may sometimes render a firm hold almost impossible, and it will be well, therefore, to slip a sterilized, thick knitted glove over the left hand.

c. A sensible patient, if warned beforehand that a move on his part may have annoying consequences, will rarely disregard such warning. I have never met with any trouble from this cause.

d. The finger of an assistant should never rest on the prostate during the operation; I consider this a fundamental mistake.

Complications that Have so far Been Observed Occasionally to Occur Sooner or Later after Operation.—1. Urethral Fever: Unfortunately, it is not in our power, in spite of most scrupulous asepsis in every particular before and during operation, always to avoid the occurrence of this complication, which is to-day looked upon as a more or less serious form of septic infection. It is evidently caused by the absorption of micro-organisms or their toxins through a superficial or deeper wound of the posterior urethra. It will be found to set in sometimes on the first, more often on the second, rarely on the third day after the operation. As is well known, in patients who are inclined that way the simple introduction of a catheter may suffice to produce it. It is all the more likely, therefore, to occur after the use of steel instruments and prolonged intra-urethral and intravesical manipulations. In favorable cases pulse and temperature will suddenly rise after a pronounced chill and then drop again within twelve to sixteen hours, without materially affecting the general condition of the patient. This I have seen only the other day in a neurasthenic subject, twenty-three years of age, who had been suffering for years from gonorrhœic prostatitis, but whose urine had been absolutely clear for the last month, at least macroscopically, although it evidently still contained bacteria. I used Bottini's cauterizator on him, after which he developed a chill at 3 o'clock in the afternoon of the second day after the operation; but his pulse and temperature dropped to normal again the next morning, after profuse perspiration. In less favorable cases the chill may recur on one of the following days, or there may be no chill at all, and only rise of temperature, after which the normal is reached again only after a distinct lysis in the course of a few days. In these instances the general condition of the patient is usually not particularly alarming.

[2] *Loc. cit.*

In malignant cases the normal condition is not reached so soon; fever will continue and then become a symptom of true sepsis or pyæmia. It is to be hoped, as Freudenberg[1] mentions, that bacteriology will here come to the surgeon's help. It cannot be doubted that one or more kinds of certain micro-organisms are responsible for the disturbance. If they could be found, we might hope to prevent the occurrence of urethral fever and its sequelæ by previously administering hypodermic injections on the basis of serotherapy.

As mentioned above, Nitze has found, in connection with his intravesical work with the help of the operating cystoscope, that gr. xv. (1 gm.) of quinine administered on the night preceding the operation exerts a distinctly prophylactic influence. Freudenberg advocates the use of methyl blue in conjunction with quinine. He prescribes gr. viii. (0.5 gm.) of quinine with gr. ii.–iii. (0.1 to 0.2 gm.) of methyl blue to be taken three times daily for two or more days prior to operation, and to be continued for a few days afterward. This certainly seems a very useful addition, in that, as we all know, methyl blue has a most powerful antiseptic influence upon the uropoietic system. Even if it should not be an absolutely reliable preventive, I believe that it would, nevertheless, be advisable always to make use of the drug.

If the fever once has occurred, it will have to be combated on general principles. The internal regular administration of urotropin, salol and quinine, also small doses of phenacetin, alcohol, strychnine, caffeine, etc., hypodermically and by mouth, for stimulating the heart's action, and the ingestion of large quantities of liquids, has given me the best results.

The more serious class of urethral fever is:

2. True Sepsis: This complication generally results fatally in older patients, especially if they have been suffering from similar attacks in former years, also from pyelonephritis. As stated in my former article, there are chronic septics among the prostatics, and in these the least cause may suffice to bring on the catastrophe. It would be gratifying indeed, if this complication could in time be avoided by the application of proper sero-therapy.

3. Pyæmia has been observed by Freudenberg. In my Case XXII. I had the peculiar experience that varicose veins on the left leg and thigh became inflamed on the third day after the operation, the immediate result having been simply ideal. This patient had passed through a tedious treatment at the hands of his family physician for a cellulitis of the hand, which, at the time of the operation, had been almost overcome. Whether multiple minute abscesses were present in his extremely soft prostatic gland, I am unable to say. I believe, however, that streptococci still circulated in his blood and produced an infected thrombus at a place where the blood-current was the slowest, *i.e.*, in the varicose veins. In a similar case I would certainly raise the lower end of the bed of the patient immediately after the operation, thus having him in a recumbent posture. As he died suddenly on the twelfth day after the operation, I believe that an embolus was thrown into his pulmonary artery or one of its branches. To my regret, an autopsy was not permitted.

4. Embolism into the lungs has been observed by Freudenberg, as proved by autopsy.

5. Absolute Retention: As I have already stated in my first article on Bottini's operation, every operator undertaking to treat his prostatic patients according to Bottini must be able to meet this complication in an absolutely aseptic manner. As will be seen further down, in Case XX., I could not enter the bladder for fully three days in any other way than by aspirating above the pubis every eight hours; thus the trocar had to be pushed into the bladder eight times. I found it very useful in this case first to penetrate transversely the thick adipose tissue with the knife under cocaine, by making an incision of about one-eighth of an inch, and then pushing the trocar through this wound into the bladder. In this way I avoided always re-entering the same tract with the trocar tube. On the fifth day at last I was able to introduce an olive-pointed Mercier with a double curve, No. 12 French, which, of course, was left in place.

6. Hemorrhage: This, if it occurs at all, is apt to set in at the time when the eschars are thrown off, that is to say, usually between the twelfth and the twentieth day, although I have in one instance seen a large piece come away as late as thirty-five days after the operation. However, I am inclined to think that here the eschar had dropped into the viscus some time previously, but had not been expelled before. On the whole I believe that, if the patient keeps quiet and the doctor abstains from washing the neck of the bladder during the first three weeks after the operation (!) this complication will rarely be observed. The introduction and tying in of the permanent catheter will almost in every instance enable us to cope with the complication. Yet a number of cases have been reported in which only immediate suprapubic cystotomy, followed by tamponade, saved the patient's life.

7. Very Frequent and Painful Spasms at the Neck of the Bladder with Partial Retention: As repeatedly mentioned in the course of my article, this is a complication rather often met with, especially in cases of a large median lobe and too short an incision. If a large projecting median lobe has been turned back by the pressing down of the beak at the time of the operation and the cut is then, for instance, made only 4 cm. long, it will be readily understood that such an incision will end within the parenchyma of the prostate itself, instead of entering the prostatic urethra, as I believe is necessary for a satisfactory result. We then have to deal with a condition similar to that found when performing immediate suture of the suprapubic incision of the bladder after the removal of a vesical tumor, the base of which had been thoroughly burnt with Paquelin's thermocautery. Experience has taught me in such cases not to sew up the bladder, but

---

[1] *Loc. cit.*

to drain it. It will be seen thus, that by learning to give our incision the proper length we shall probably be able to avoid the occurrence of such painful and frequent desire to urinate. In case it does set in, large doses of morphine with suppositories of opium and belladonna, extr. hyoscyami in two-grain pills at regular intervals of four to six hours, may be found valuable. If the catheter enters without great difficulty, it ought to be introduced every six or eight hours according to necessity. If the desire to empty the viscus should be too frequent, the catheter must be left *in situ*. In that case, provided there is no chronic pyelitis present, which so often causes fever, we have to watch the temperature carefully; for a rise, as I have seen, may be the precursor of a funiculitis with abscess formation of the same or of the testicle. The catheter should be removed just as soon as a rise of temperature occurs. If the patient does not begin to urinate voluntarily within a reasonable time after the operation, the latter will have to be repeated.

How Soon Should the Operation be Repeated if the Result of the First Operation was Not Satisfactory? — This question certainly is of very great importance. To answer it definitely is impossible at the present time owing to lack of sufficient experience. Then, too, there are individual differences that have to be considered in each case. Of course, if, as just stated, the first cauterization of the gland produced continuous, painful vesical spasms, accompanied by inability of the patient to empty the viscus sufficiently, a second operation should be soon performed. The unceasing and undiminishing suffering of the patient will here have to be the guide. Thus it became necessary for me to repeat the operation in my Cases VII. and XX., eighteen and twenty-nine days, respectively, after the first interference. In Case XXI., in which I thought I should have to do a prompt instrumental revision, I could temporize on account of the steady improvement that set in on the eighth day after the operation.

On the other hand, if the suffering of the patient be not the immediate cause for a second operation, if the amount of residual urine still present is the only indication, the decision as to when to repeat the operation is far more difficult. Many patients will be perfectly satisfied as soon as the frequent painful spasms at the neck of the bladder are relieved, and will not care about the residual urine, no matter how large the amount may be. And that Bottini's operation can remove these pains, and permanently, is absolutely certain. The proposition to repeat the operation at a later time will, therefore, often meet with opposition on the part of the patient. He naturally shrinks from going through a second operation as long as the former ever-present pain no longer constitutes a *causa movens*.

In patients with large fibrous prostates in whom the first operation did not effect the entire removal of residual urine, we should not be, it seems to me, too hasty in repeating the operation. I have seen a case, that of a man seventy-one years of age, a pronounced diabetic (eight per cent.), getting decidedly worse after the third operation when the second had brought great improvement. I have mentioned that, if we make our incision to correspond to the difference in length between the normal urethra and that of the given case, as explained fully in the foregoing pages, we may hope to help our patients at once. If it be found that an incision longer than 4 cm. be necessary, while the instrument at hand permits only of cutting 4 cm., the surgeon had better temporize. The case just referred to has made a very strong impression upon me, so that I would venture to give warning to my colleagues, although my experience is based on one case only. In this instance the prostate was extremely hard and did not yield a bit to pressure. At present the patient passes but a small amount of water voluntarily during the day. However, all his many pains and annoyances prior to the Bottini's operations have been overcome by catheterizing himself twice in twenty-four hours. He now lives a comparatively comfortable life. Catheterization, which had been practised for seven years, is much easier than it was ever before. Of course, had I made my incision sufficiently long at once, and had I burned the posterior groove twice in succession, the result might have been entirely different.

Recurrence.—It is, no doubt, too early to say much about this question. Bottini claims not to have seen a single recurrence in all of his more than eighty cases. As stated in my former article, it is to be regretted that he never gave a careful synopsis of his experience. Nobody, therefore, can blame the man who shakes his head when reading that, even in preantiseptic times, this operator never met with any complications in his patients. Nor will it be taken amiss if he should express his doubts as to the correctness of the statement that a recurrence was never seen. It certainly would seem necessary to have reports on re-examination at a later period.

In my eleven cases which belonged to the category of "so far cured," I have seen but one case in which at present the trouble has returned to some degree, and which now is about as it was a short time before the operation, at least as far as frequency of micturition is concerned. This patient (Case XI.), however, was operated upon at the time when I still used the original small battery, which did not enable me to read the strength of the current from an amperemeter during the operation. I therefore cannot claim that the four cuts were made with the same strength of the current throughout. In fact, I rather incline to the belief that this was not so, for the reason that this is the only one of my cases, so far observed, in which the trouble has reappeared to some extent. I have, of course, advised the patient to undergo a second operation. He, however, refused to have it done, being satisfied with his present condition. In this respect also, Freudenberg's latest article is of particular importance, for he, too, has carefully traced his cases. In eleven out of the twelve selected cases published by him—of which six were operated upon once, three twice, and two three times on account of a previously insufficient result—the cure obtained by the last operation, that established perfect vesical drainage, is reported by him to be still lasting and unchanged. In five of these the operation was done as long ago as thirty-one, twenty-six, twenty-two, twenty, and sixteen months; in the other six it was done less than a year since. In the twelfth case the result of the operation was negative, the retention not having been overcome. Thus the foregoing shows that in the oldest case, *i.e.*, the one in which the operation dates back furthest, the perfect condition primarily brought about by Bottini's operation has so far continued absolutely unchanged for over two and one-half years. I personally can prove the lasting effect of the operation in my patients, who were primarily cured of all their subjective and objective symptoms—in one only the vesical catarrh did not entirely disappear—twenty-two, twenty-four, and twenty-five months after the operation (Cases V., VI., and VII.).

The Advantages to be Derived from Bottini's Operation Aside from its Main Purpose, *i.e.*, the restoration of vesical drainage, are: (*a*) The disappearance of the vesical spasms; (*b*) cure of the generally present chronic constipation; (*c*) improvement in general condition, as shown by increase in weight.

a. As I have stated in a former article, Bottini's operation seems to me to take the same place in regard to the spasmodic contraction of the sphincter-vesicæ muscle, as forcible stretching or division of the sphincter-ani muscle takes in connection with anal fissure. The muscle is divided in two or three places and therewith comes to rest. Furthermore, the threefold division of the glandular tissue interferes with the former blood supply of the gland, and thereby prevents the intermittent "congestion" (Guyon), the cause of the recurrent attacks of cystitis and acute retention.

b. It is interesting to observe how almost invariably the chronic constipation these patients so frequently suffer from disappears after Bottini's operation, even though the latter has been but partially successful. This is probably attributable to an improvement in the nervous condition of the patients. For with the cessation of the former continuous spasms at the vesical neck, the irritability of the nerves supplying the lower sigmoid and rectum will also disappear, and thus the normal function be restored.

c. An other striking feature observed in connection with Bottini's operation is, that in nearly every instance the patients gain in weight, and that even in cases in which the obstruction to the proper flow of urine has been but partially or not at all overcome. Every one of my patients illustrates this point. It is explained, I believe, by the fact that these poor sufferers, who sometimes for ten or fifteen years have not known what a fair night's rest means, are again able to sleep five or six, sometimes eight to ten hours in a stretch. Their nervous system at once recuperates, and this naturally reacts upon all other functions. Freudenberg has paid considerable attention to this interesting phenomenon, and proves his observation by figures. Thus, one of his patients, in whom the operation was performed twice but the functional results remained *nil*, wrote him that everybody considered that he looked younger by ten years, and that he had gained thirty pounds within about two years.

What Constitutes a Cure after Bottini's Operation?—The three factors that, in my opinion, would determine an ideal cure of a prostatic are:

(*a*) Removal of the obstruction to the outflow of the urine; in other words, complete elimination of residual urine, or reduction of the same to an insignificant amount; (*b*) return to normal frequency of micturition; (*c*) disappearance of vesical catarrh.

As regards *a*, the mechanical effect of the operation, of course, must remain the decisive factor. So long as the obstruction is not satisfactorily removed, the surgeon has no right to consider his patient cured. However, it should be remembered that it is more or less within his power to accomplish this result by repeating the operation, or, if need be, doing it a third time. The patients' demands are not, as a rule, very exacting. So long as they have been relieved of their former continuous suffering, they consider themselves cured, even though there still be a residual urine of 250–300 c.c. (eight to ten ounces). From a scientific standpoint, such a definition of the meaning of a cure is, of course, untenable.

With regard to point *b*, the re-establishment of normal frequency of micturition, this evidently depends upon the success or failure of the surgeon in removing the residual urine and the vesical catarrh or pyelitis. In proportion to the degree to which one or the other or both of these factors have been overcome, will the frequency of micturition be reduced. To give any exact figures as to what constitutes "normal frequency" would be impossible, since this must depend largely upon the total quantity of urine passed within twenty-four hours. A diabetic, for example, or a man with a contracted kidney will probably urinate twice or three times as often as one not so afflicted, although the residual urine may have been removed in the latter as well as in the former.

Now, as regards the vesical catarrh, this disappears in exceptional instances as a direct result of the operation, *i.e.*, as soon as the obstruction to the proper outflow of the urine has been removed. In other cases careful after-treatment is imperative. The administration of the different drugs so often mentioned in the course of this paper, aided by local irrigation —best with increasing doses of nitrate of silver— will often clear up a patient's urine that has been turbid for years. Nevertheless we should not be surprised if our efforts in this direction are not always crowned by success, even if pyelitis be absent. Whoever has looked through the cystoscope into the trabecular bladder of a prostatic, with its larger and smaller acquired diverticula, its numerous and deep grooves between and behind the protruding bundles of the detrusor muscle, will understand the difficulty, nay, impossibility, in some instances, of curing an infectious catarrh that has once been thoroughly grafted upon such a surface. However, it has been my experience that patients in whom the urine remained more or less turbid after Bottini's operation are not, as a rule, in the least disturbed by this condition. They have no pain; they are well able to retain their urine when the natural call comes; they have no tenesmus. If they did not see their urine, they would not know that they had a catarrh; in other words, if the catarrh should disappear, this would cause no difference to them as far as their feeling is concerned. I personally have observed the entire disappearance of all turbidity in the urine in five of my cases. In these the urine cleared up by itself after the removal of the obstruction, without any further vesical irrigation, the patients merely having continued taking salol and urotropin internally. In none of the remaining cases, however, was I able to carry out a suitable after-treatment. All of them left my immediate supervision three to four weeks after the operation.

Indications for Bottini's Operation.—I have purposely reserved the discussion of this question because it is by far the most important of all.

The principal decision the surgeon is called upon to render in the case of a patient with hypertrophy of the prostate who needs radical relief is: Which of the many operations in vogue for this affection is indicated?

Simultaneous ligation of the internal iliac arteries— a procedure which certainly belongs to the radical operations, in my estimation—has been abandoned on account of the severity of the interference in old patients, and the possible complications arising.

Castration, an operation which has brought permanent relief to many prostatics, is losing ground owing to the objections offered by the patients, many of whom have heard that there are other means at our disposal, nowadays, to help them. It also seems inadvisable to propose the operation, because quite a number of patients thus treated have become mentally affected.

Ligation of the vasa deferentia (including resection of the spermatic nerves—angioneurectomy) has received a severe blow by the compilation of cases from Mikulicz's clinic, in 1897, by which, as will be remembered, it was found that even in cases with, at first, favorable result, the old trouble recurred at about the end of the first year. In my former two articles I expressed the opinion that the preliminary performance of vasectomy might be a rational procedure in order to reduce the hyperæmia of the prostate gland. In my twenty-four cases I have worked upon this basis in two instances, but must confess that I have not been particularly impressed by this method; at least I have no proof that it has been of value. In the second patient treated in this way (Case XIX.), in which I left a permanent catheter in the urethra for five days, a suppurative funiculitis set in, which it was very interesting to see stopped short at the point of ligation and division of the vas deferens. Here the suppuration following gave me a good deal of trouble during the after-treatment, inasmuch as it took almost half a year before the sinus definitely closed. I am, therefore, rather inclined now not to let this interference precede Bottini's operation.

Prostatectomy, suprapubic or perineal, will, I believe, at the present time be advisable only in cases of large, fibrous prostates, provided the patients are not too far in the seventies and seem able to stand an operation under general anæsthesia.

It is interesting to note the marked divergence of opinion with regard to the value of Bottini's operation in patients with a fibrous prostate. Morton, of Brooklyn, when publishing his five cases of hypertrophy of the prostate treated by Bottini's operation, expressed the view that only fibrous prostates were amenable to improvement or cure by the said method. Also, a renowned American surgeon, after much reflection on this subject, wrote me the other day that it was his belief that hard prostates only could be relieved by Bottini's operation. On the other hand, I personally have seen the most beautiful results in those patients in whom the glandular enlargement preponderated, and had less success when operating on patients with a hard gland. A similar divergence of opinion as to the effect of Bottini's operation still exists in regard to the significance of the amount of residual urine. Lohnstein in a résumé covering the experience of many operators claimed that the best results are obtained in cases of absolute retention, while I personally have had more success in cases with incomplete retention. Thus it will be seen that the class of cases that were most successful in the hands of one operator proved less so in the hands of another—a circumstance that, in my opinion, speaks well for the operation, since it demonstrates that *each* type of prostatic enlargement with its varying clinical symptoms has shown good results in the hands of *some* operator. Of course, this may be perhaps, to some extent, explained by the fact that no two cases of prostatic enlargement are exactly alike. Further experience of individual operators is absolutely necessary, before it will be possible definitely to settle the points here under consideration.

The question, when Bottini's operation shall be done, I would to-day answer in the same way as I did eighteen months ago: namely, as soon as it will become necessary to give the catheter into the hands *of the patient himself*. As I have said in my previous paper on this subject, the danger to life begins at this period. A single mistake in regard to asepsis may set up an incurable cystitis with pyelitis or pyelonephritis. That the surgeon will be able to avoid these complications by doing Bottini's operation on a patient with a hitherto uninfected urinary system can, of course, not be guaranteed. Yet if the work was properly carried out, under the most scrupulous asepsis, I do not think it likely that the complications mentioned should set in.

I do not share the view expressed by various authors, that Bottini's operation is absolutely contraindicated in the presence of a pyelitis. Among my twenty-four cases there certainly were at least two in which a marked degree of uni- or bilateral pyelitis was present. Both patients stood the operation very nicely, the one being absolutely cured, the other much improved. Nevertheless it is certainly necessary to make it plain to the relatives, if not to the patient himself, how greatly the risk is enhanced in the presence of pyelitis.

That Bottini's operation is a safe and harmless procedure, as might be inferred from the original publications of the author of the operation, will no longer be claimed by any one in view of the experience of operators all over the world. It will have its deaths, if done in more or less advanced cases, the same as every other operation so far devised for prostatic enlargement has had. However, it should be remembered that a comparative compilation of the cases of the various authors up to date shows Bottini's operation to have had the lowest mortality, while at the same time it shows the greatest percentage of cures. And I believe we shall be able to decrease considerably even the present low rate of mortality, by making use of the experience we have meanwhile acquired, and by advising an early operation, that is to say, as soon as unmistakable clinical symptoms have appeared. Whenever the doctor finds the premonitory symptoms of prostatic enlargement slowly developing, he should insist upon a distinct diagnosis of the trouble. At this stage, too, the diagnosis can be made with absolute certainty with the aid of the cystoscope. If that well-known groove at the internal urethral fold at the neck of the bladder is seen during cystoscopy; if, furthermore, there are symptoms of a beginning trabecular bladder, in cases in which the catheter repeatedly finds a small amount of residual urine, the diagnosis, according to my belief, is definitely established. These cases, as Freudenberg so well says, are not yet ripe for the incisor. Nevertheless, from a prophylactic point of view it would be well for the patients if the indication for radical treatment even at this early date could be established. I refer to the use of Bottini's prostatic cauterizator.

As is known, Freudenberg has also, within the last year, improved the original cauterizator of Bottini with reference to aseptic principles. It can now be boiled the same as the incisor, and is a reliable instrument. It shows two platinum blades, resting on a porcelain plate, at the concavity of the junction of shank and beak, which can be brought to red or white heat by the electric current.[1] If these blades are pressed against the projecting prostate at the neck of the bladder, a slight or stronger effect can be produced, according (*a*) to the amount of pressure used, (*b*) to the amount of heat applied, and (*c*) to the length of time the cauterization is made. It will be readily seen that a great amount of prostatic tissue can thus be burnt away right at the neck of the bladder and the prostatic bar just appearing lowered down to the base of the bladder. It is further evident that such a surface cauterization does not share the certain amount of risk attached to the interference with Bottini's incisor. The only complication, the operation otherwise being aseptically carried out, might be hemorrhage at the time when the eschars are cast off, and this can here be more easily coped with than when occurring after the ordinary Bottini operation. According to the author, one must not be surprised to see improvement begin as late as at the end of the third or fourth week, in some instances. However, even if future experience should prove the aforegoing assumption to be correct, it is more than questionable whether doctors will be ready to propose such an operation to prostatics in the early stage of the disease, and whether the patients will accept such advice. I fancy that time is far distant; perhaps it will never come. Yet I am inclined to believe, with Freudenberg, that such an early cauterization of the beginning prostatic enlargement would have to be looked upon as an operation void of all danger, which bids fair to save the patients thus afflicted all the untold suffering that is otherwise bound to come sooner or later.

(To be concluded with report of cases.)

---

[1] The improved instrument was demonstrated by me before the Section on Surgery of the New York Academy of Medicine, December 11, 1899. See MEDICAL RECORD, December 30, 1899.

THE PAST AND PRESENT OF REFRACTION.

By FRANCIS VALK, M.D.,

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

SOME years ago I had the pleasure of reading a paper before the State Medical Society on "Our Refraction Cases," at a time when the objective examination of the dioptric apparatus of the eye was just beginning to demand the attention of the profession, and in that paper quoted these words: "It has the misfortune to depend for its promulgation and practical application upon the specialist, and almost upon the specialist of a specialty, and this in a profession and in an epoch in which it is fashionable to sneer at specialism and at the specialist who dares to plead for the truth he knows—and that at first, at least, only he can know." Yet to-day how materially all our work has changed!

Before that time we had no objective methods of quickly ascertaining what was the refractive condition, except by the use of the ophthalmoscope, and in reference to the use of this most excellent instrument for the estimation of refraction I may state that at that time, in a case fully under the influence of a complete mydriatic, examined at the Manhattan Eye and Ear Hospital by all the surgeons and attending physicians, out of nearly twenty records only two were very near the exact refractive condition as shown by the "trial by glasses," while all the others concluded that the case might vary in all the degrees of myopia to hypermetropia, two exactly opposite conditions. Hence only a decade ago all ophthalmologists were compelled to rely, almost constantly, on the use of atropine to paralyze fully the action of the ciliary muscle, and then to depend on the statements of the patients examined as to what glass would secure the best vision and correct the refractive condition. This was considered the crucial test, to be followed by ordering the glass that would be accepted after the effects of the cycloplegic had passed off. All this would require three careful examinations, at the same time depriving the patient of the use of the eyes for distinct vision for about ten days.

It is very true even at the present day that the use of atropine in refraction is the crucial test, and the examination of the refraction under this mydriatic leaves nothing to be desired, but, except in the case of children, it causes extreme inconvenience to others, and has a certain amount of danger when used in old persons; while to-day, in many cases, it is not needed.

In 1876 the late Dr. C. R. Agnew, whom every one remembers for his kindness and admires for his skill, published a monograph on "One Thousand Cases of Asthenopia," in which he reported two hundred and eighty-one with normal or emmetropic eyes and four hundred with hypermetropia and its complications; but at the present time how few cases of emmetropia do we meet in our daily work—almost none at all. So seldom do we find these cases that some of our best men have concluded that this condition of the refraction does not exist; that the hypermetropic eye, of low degree, is truly the emmetropic eye. This is a proposition I do not fully indorse, as we do at times find an eye that is perfect in reference to its vision and its refraction, and this, in my estimation, must always represent the standard eye. We do meet these cases in our clinical work and in the office, not often, I must confess, but we must remember that the human beings so fortunate as to have emmetropic eyes either do not, or rarely do, need the services of an oculist. They never have any symptoms of asthenopia, so we do not have the opportunity to test this vast number we believe must exist, and if they do need glasses it is only when old age has come to them; when they have passed the age of forty or forty-five years, their "arms are not long enough," and almost any simple convex glass will give the necessary reserve power to see at their reading distance, only requiring a slight change every three or four years.

We had other tests in those days besides the ophthalmoscope, as that of Green's, with the radiating lines, that was useful in myopic astigmatism, but in my opinion in that condition only; also Placido's disc and the cobalt blue test; but all these, as you are well aware, depended entirely upon the statements of the persons examined. As I look at my records of those days and at my notebooks of to-day, I am sure we must have but imperfectly corrected the refraction of very many cases.

It was not until about 1885 that we began to realize the importance of the objective examination of the dioptric apparatus, though the same instruments of precision were in use as at the present day, in the private offices of several ophthalmologists, yet those who possessed them seem to have placed very little reliance upon their use until the past fifteen years.

When I published the results of my examinations of the first one thousand cases, they were as follows: Hypermetropia, 351 cases; simple hypermetropic astigmatism, 192; compound hypermetropic astigmatism, 165; compound myopic astigmatism, 90; myopia, 75; emmetropia, 54; mixed astigmatism, 49; simple myopic astigmatism, 26; "giving a total of 2,004 eyes examined, of which I found that in 774 cases the refraction error was the same in each eye, and in 174 cases the refraction error was different, or the condition of anisometropia, the largest percentage being in the cases of mixed astigmatism. In all statistics of refraction the hyperopic eye stands foremost in numbers," but do we find it so at the present day with our improved methods of examination?

All the above examinations were carefully made according to our knowledge of refraction at that time, but I feel very positive that if I would take the results of my last examinations of one thousand cases from my case-book I would find the figures very different, and simple hypermetropia would not stand at the head of the list, for it is in the diagnosis of this condition that I find the most pronounced changes.

About 1885 I commenced the study of the method of retinoscopy, or the so-called shadow test, with Dr. George J. Bull, who is now associated with Javal of Paris, and recommended it to the profession in a paper read before the County Medical Society in February, 1890. At that time we had no retinoscopes, but simply pieces of looking-glass to observe the phenomenon that was shown in the pupillary space. This was the first practical test that we had for the objective examination of the total refraction, and in my hands it has been in constant use ever since, and to-day, fifteen years afterward, I still consider it one of the best tests in the hands of the oculist for the examination of the refraction. By the use of this instrument—as we notice the movements of the retinal reflex as it passes across the pupillary space—we estimate the refraction of the entire dioptric apparatus, or, in other words, the parts of the eye through which the rays of light pass in the act of seeing both at the distant and near points of vision. Wishing to carry this test to its full completion, we may place glasses before the eye until we neutralize the movements of the reflex in the two principal meridians, testing each meridian separately, and the glass so placed will very nearly indicate the refraction. In this way we rapidly and accurately note the existence of any astigmatic error, its amount in diopters, and the axis of the correcting glass.

About 1890 my honored friend, Prof. D. B. St. John Rossa, brought from Europe one of Javal's ophthalmometers, and, though there were several in use in this country, yet it was due to his persistent and earnest advocacy of this most excellent instrument that its use has spread and extended from one end of the country to the other, and at the present time no oculist's armamentarium can be complete without one. Hence I feel that to Dr. Roosa all honor is due for the introduction, in this country, of one of the most valued objective instruments for the diagnosis and measurements of corneal astigmatism. As this condition almost always exists in the anterior surface of the cornea, its findings can be relied upon with almost positive exactness in reference to the axis of the glass and the amount of the astigmatism. I published a full description of this instrument in my book on the "Errors of Refraction," in the issue of 1890, and since then—though many improvements have been added by others, in its mechanical advantages only—no changes have been made in the use of the ophthalmometer for the diagnosis of corneal astigmatism.

I also remember that about fifteen years ago we began to hear rumors of the relief of certain reflex symptoms by the use of glasses. One physician, speaking to me on the subject, said a certain physician "could relieve corns by the use of glasses," a very sarcastic remark in reference to the work of a brother physician; but in spite of the opposition, at that time, to the influence of the eye upon certain reflex symptoms, perhaps clearly indicated, the work was still going on; effects and results were noted; some cases with certain reflex symptoms were relieved by the correction of the refraction error, but in others the glasses failed to give the required relief, and our attention was turned to the movements of the eye in reference to its power of fixation. Then Dr. George T. Stevens demonstrated that many nervous phenomena were due to the want of balance in the movements of the eyes, one to the other, and he gave us the excellent nomenclature so frequently in use at the present time. So heterophoria has taken its place as one of the causes of certain reflex phenomena that may be relieved by the correction of that condition. Hence the tendency to a deviation of the visual lines has been established, more or less, in this special branch of medicine, and no examination of the eyes is complete until the power of "duction" has been fully studied, and, if need be, corrected. While I appreciate the great advances Dr. Stevens has made in his study and explanation of this most intricate condition of heterophoria, and while I think his nomenclature of these various conditions, so frequently found, is all that could be desired, yet I cannot say I fully commend his methods of diagnosis. In my private as well as clinical practice, I prefer to base all my conclusions in reference to the action of the ocular muscles, as regards their power, on the old and simple prism test, firmly believing that nature intended there should be a certain balance of power between the action of the antagonizing muscles of the eye, and in which we may expect to find a certain standard in the power of the muscles one to the other.

In the finding of this standard condition, orthophoria, then, we will have no muscular asthenopia; and all this has to-day convinced me that we should have three fields for examination, namely, the field of vision, in which we estimate its quantitative and its qualitative extent; the field of fixation, in which we estimate the excursions of the eyeballs within the field of perfect vision—in other words, the extreme limit of the visual lines in all and every direction with perfect fixation, this being about 90° laterally and vertically; and lastly, we have the field of fusion, a region shown and estimated by the prism test, representing the power to fuse, upon the macula, rays of light falling upon other parts of the retina. This field is generally found to be, taking the macula as a centre, about 30° outward, 8° inward, 2° upward, and 3° downward, forming what I consider the normal field of fusion, controlled by the guiding sensation or fusion force of the retina and limited by the individual power of the eye muscles.

The last two fields have attracted much attention from the profession within the last few years, and they seem to be controlled by separate centres of the brain. The extent of the field of fixation is a voluntary act, while that of the field of fusion is, to my mind, involuntary, as no force of the will can make the images fuse beyond this certain extent, though it may be extended in certain directions by constant practice.

All this shows what the past of refraction has given to us; and now what is the present state of refraction to-day? Do not all these exact and useful objective methods, all the advances in the examination of the eye and our better understanding of the ocular movements, show that we can now, in almost all cases, estimate the true and total refraction of the eye without depending upon the subjective tests—in fact, correct the refractive error without asking a single question of our patients? I have done this over and over again in my clinical work, and afterward proved it by the subjective examination, by the ready acceptance of the glasses, or by the crucial test, the use of atropine, and the test by glasses.

To do all this requires many hours of constant practice in the examination of our cases; the eye of the examiner must be trained to know and to appreciate all it sees, just as the fingers of the surgeon, by their delicate touch and skilful manipulation, will indicate the diagnosis, and the surgeon will know, almost to a certainty, what is the condition of the underlying parts he examines. We may look through the aperture of the ophthalmoscope and see the details of the fundus, but that will by no means tell us what is the refraction. This we must estimate by the appearance of the most delicate parts of the retina as the correcting glass is placed before the aperture, and this must be done in the principal meridians of the eye. In my opinion the oculist who can diagnose and estimate the true refractive condition in a case of mixed astigmatism has truly learned and mastered one of the most useful instruments in our hands.

Then with the retinoscope we can quickly see and estimate the true and total refraction in the two meridians as we note the reflex as it passes across the pupillary space, and we can confirm all this by the examination with the ophthalmometer, at the same time showing the corneal curve by the length of the radius, in which we may find a clew to the refractive condition; and finally we conclude our examination by testing the eyes for any want of balance in their movements in reference to the fusion power. After we have corrected all these findings, brought about normal vision and normal balance, we may reasonably conclude that, if relief is not obtained, the eyes cannot be at fault, and the reflex symptoms must be due to some other cause.

And now, as we look over the notes of refraction in our books, we find that hyperopia, pure and simple, is not the leading refractive condition; that in the vast number astigmatism, both simple and compound, stands at the head of our list, which, when corrected, may give success in many cases; that if we fail with the use of glasses we may find some unbalance of the ocular muscles that can be adjusted; and that, having placed the eyes in the condition originally intended by nature, we may feel confident that our work has been performed in a truly scientific manner.

Projectiles of hard exterior are more humane than the old leaden bullet, and amputations are not so often required, while less cripples are returned to the state. This agrees with recent experiences in Cuba. —Major Louis A. La Garde.

PROGRESSIVE PERNICIOUS ANÆMIA AND MALIGNANT DISEASE OF THE STOMACH.

By ALBERT ABRAMS, M.D.,

SAN FRANCISCO.

In the cases of pernicious anæmia counterfeiting carcinoma of the stomach, culled from the medical literature, I can find no instance in which simulation has been more marked than in the two cases which have been made the subject of this contribution.

Case I.—A man aged forty-three years, referred by Dr. W. Barrett, of Redwood City. The patient for more than a year has grown progressively weak. He suffers from dyspnœa, palpitation of the heart, and gastric irritability. He has lost twenty pounds in weight. The status præsens in brief is as follows: Marked pallor; malleolar œdema; hæmic murmurs at the cardiac base and in the cervical veins; slight evening exacerbations of temperature. The stomach contents, after an experimental meal of Leube, shows the absence of hydrochloric acid and the presence of large quantities of lactic acid. Palpation reveals marked tenderness in the region of the pylorus, and percussion easily demonstrates ventricular dilatation. The glands of the neck and inguinal region are slightly enlarged. In this patient a pulmonary lesion was suspected, and in the absence of palpable physical evidence he was submitted to a Roentgen-ray examination. The rays demonstrated a dark patch in the apex of the right lung. The question naturally arose whether in this patient I was dealing with the anæmia of the pretuberculous stage of phthisis, a condition of the blood which I have designated elsewhere as pulmonary anæmia.[1] Pulmonary is distinguished from all other forms of anæmia, the one exception being pernicious anæmia, by the fact that while the ferruginous preparations benefit pure anæmics, in pulmonary anæmia they are practically of no value, or at any rate the benefit accruing from their use is only evanescent. The pathognomonic sign of pulmonary anæmia is the therapeutic test. If a suspected individual is subjected to a single pneumatic treatment, employing inhalations of compressed air, one invariably finds, after an examination of the blood, an increase in the percentage of hæmoglobin. A collective investigation made by me, in a number of patients demonstrated that the hæmoglobin percentage could be increased fifteen per cent., on an average, after a single pneumatic-cabinet exercise. This test proved negative in my patient.

Case II.—A woman aged seventy-four years, seen in consultation with Drs. von Hoffman, Thorne, De Vecchi, and Aronstein of this city. The symptoms were similar to those in the previous patient, excepting that there were more pronounced emaciation and gastric irritability. Vomiting in the incipiency of the disease was of daily occurrence, and repeated examinations of the vomitus invariably demonstrated the absence of hydrochloric acid and the presence of lactic acid. One of us detected the presence of an intumesence in the pyloric region, while all concurred in the demonstration of increased sensitiveness and resistance in that area. Pronounced cachexia was present, but there was not the characteristic yellow lemon tint of pernicious anæmia. The foregoing anamneses were decidedly suggestive of malignant disease of the stomach, and would, in the prehæmatological era of medicine, be accepted as conclusive clinical evidence of its existence.

The following differential table. taken from the excellent text-book of Anders on the "Practice of Medicine," suggests the conventional evidence employed in differentiating obscure gastric carcinoma from progressive pernicious anæmia:

Pernicious Anæmia.	*Gastric Carcinoma.*
Red corpuscle count falls to, or below, 1,000,000 per c.mm.	Count does not fall to 1,000,000, as a rule.
Found earlier in life.	Occurs after middle life.
Gastric symptoms not pronounced.	Gastric symptoms more suggestive.
Lemon-tinted skin common.	Skin pale, muddy, or jaundiced.
Adipose tissue fairly preserved.	Progressive emaciation.
No glandular enlargement.	Supraclavicular or inguinal glands enlarged.
No physical signs over stomach.	Increased area of resistance over stomach.
Gastric contents after test meal negative.	Deficiency or absence of hydrochloric and presence of lactic acid.
Some improvement may be brought about, even cure, though rarely.	Condition becomes steadily worse until death ends the case.

To the foregoing table the dictum of Osler may be added: "In carcinoma of the stomach, the condition is an anæmia with wasting, and the layer of panniculus is not retained as in the ordinary forms of pernicious anæmia."

Hæmatology has won so many triumphs in modern medicine that no clinical examination may be regarded as complete without a methodical blood examination. Cabot, in his monograph on the blood, gives expression to the following epigrams: "Malignant disease may bring down the blood count to 1,000,000 or lower, but in such cases leucocytosis is always present"; on another page: "In pernicious anæmia, the leucocyte count is very low and may fall below 1,000 cells per cubic millimetre." A few years ago, the preceding statements would have been regarded as the utterances of a doctrinaire, yet now clinicians everywhere accept them as truisms.

In the first patient, the blood count showed 1,000,000 erythrocytes with a hæmoglobin percentage of 40, or a color index of 2. The leucocyte count was reduced to one-third the normal. In the second patient, besides the presence of normo- and megaloblasts, the red cells were reduced to 800,000 per cubic millimetre, the hæmoglobin to thirty-five per cent., and the leucocytes to one-half the normal number.

Both patients were placed on increasing doses of Fowler's solution and bone marrow. The latter had to be discontinued at once owing to the gastric irritability which it provoked. The therapeutic test with arsenic only confirmed the evidence of the blood examination (marked reduction in red corpuscles, leucopenia, and high color index), and the improvement in both patients was immediate and progressive. The first patient returned to his work as a laborer, and when I last saw him he said, "I can work harder than I have for years." He took twenty drops of Fowler's solution three times a day for two weeks, and the number of his red corpuscles at the end of that time increased to 500,000 above the normal. The same marked improvement, though not so rapid, was noted in the second patient, and hydrochloric acid reappeared in the stomach contents.

The following conclusions may be formulated:

1. Arsenic is a true specific in pernicious anæmia, and is as certain in its immediate results as is mercury in syphilis, quinine in malaria, or iron in chlorosis. The specificity of arsenic is so great that in no case of grave anæmia are we justified in excluding the progressive pernicious variety, even though the blood examination is negative, without a heroic trial of arsenic. Like the other specifics, it produces relative cures and cannot be regarded as a prophylactic owing to the frequent relapses which occur. It may be given as Fowler's solution, beginning with three-minim doses well diluted after each meal, and increased by one or two minims daily according to the urgency of the case,

---

[1] Medicine, December, 1895, and The Medical Standard, January, 1900.

until twenty-five or thirty minims are taken three times a day. A safer rule is to push it to the point of toleration and maintain it at this point until the blood examination shows the result desired. The appearance of its physiological effects (œdema and itching of the eyelids, gastro-intestinal irritation, etc.) is a signal for its temporary discontinuance. When arsenic cannot be given by the stomach, it may be administered subcutaneously or even by the rectum.

2. In association with arsenic, assimilable food and rest are indispensable adjuvants.

3. The use of intestinal antiseptics in this as well as in other diseases is a mere therapeutic refinement not sanctioned by bacteriological reasons, and they ought, therefore, not to be employed as a routine measure. In the Italian literature one finds some authentic evidence of the good effects from thymol, its administration being suggested by the theory that pernicious anæmia is caused by intestinal absorption of products which are destructive to the red blood corpuscles.

4. Iron is not only useless but is apt to create digestive disturbances.

5. Bone-marrow is said to be curative, but in my experience it induces nausea and aggravates existing gastro-intestinal troubles.

6. Gastric disturbances suggest stomach lavage. The character of the food ingested must be determined by the results of a chemical analysis of the stomach contents.

7. To counteract the great reduction in the quantity of blood (oligæmia) weak saline solutions may be given by the colon (enteroclysis) or preferably in the subcutaneous tissue (hypodermoclysis).

8. Relapses are best prevented by minute attention to dietetic and hygienic details.

784 Geary Street.

Contribution to the Knowledge of Some New Remedies.—Overlach describes the advantages of fortoin as: Its taste has not the biting sharpness of cotoin crystals; it is a stronger antiseptic. It is formaldehydcotoin or methylendicotoin. It is formed by the action of formaldehyde on cotoin. It consists of beautiful yellow crystals. The fusing-point lies between 211° and 213° C. It is easily soluble in chloroform, acetone, and glacial acetic acid, difficultly soluble in alcohol, ether, and benzol, insoluble in water, but very easily soluble in alkalies. It is an expensive remedy, but reliable after the failure of other measures.—*Centralblatt fur innere Medicin*, March 10, 1900.

Application of Forceps in the Dead Mother; Living Child. Remarks on Death in Labor and Delivery in the Upright Position on Account of Orthopnœa.—Alfred Egon Neumann reports the extraction of a living child from a dead mother. The child showed scarcely a trace of asphyxia, soon cried, and lived. The case of orthopnœa was that of a woman forty years old. There was general œdema; systolic and diastolic cardiac murmurs were present. Urine was spare in quantity, with one per cent. of albumin. After delivery, the patient was tapped, and then improvement began. On the ninth day there was still one-half per cent. of albumin, with no casts. The œdema had almost disappeared.—*Centralblatt für Gynäkologie*, March 10, 1900.

The Mechanism of the Action of the Anti-Diphtheritic Serum against the Toxin in the Animal Organism.—Nicola Pane believes that instead of exerting a chemical influence, as do some other serums, the anti-diphtheritic serum produces a relative and temporary immunity in the organism by exciting special defensive powers in the cells. This immunity is not essentially different from that caused by the toxin introduced into the body in non-lethal doses, except that the latter works more slowly and is much more lasting in its effects.—*La Riforma Medica*, March 15, 16, and 17, 1900.

On the Therapy of Epilepsy with the Flechsig Method.—Lad Haskovec states that the cases he describes show that the bromine therapy in connection with a properly regulated life has a good influence on the course of epilepsy. The combination of opium and bromine, potassium bromide, as Flechsig directed, give good results. Diet has a great influence and should be carefully regulated. The milk diet is considered very efficacious. More time is yet needed wholly to prove the benefits of Flechsig's method.—*Wiener klinische Rundschau*, February 25, 1900.

The Association of Paraldehyde with Chloroform.—Cosimo Noto believes, from the results obtained by experimentation, that the association of paraldehyde with chloroform to produce anæsthesia completely suppresses the period of chloroform excitement, prevents profuse secretion of saliva, and causes anæsthesia in a very short time and with a small dose of chloroform. The sleep is sound, respiration calm, heart regular, and blood pressure sufficiently strong. The sleep is much prolonged, even after the cessation of anæsthesia; the patient awaking some time after the operation is over, already revived and without suffering the effects of trauma.—*New Orleans Medical and Surgical Journal*, March, 1900.

A Case of Total Laryngectomy for Sarcoma; External Artificial Larynx.—N. Taptas records the case of a woman, aged forty-six years, who had suffered from hoarseness for three years, and who had worn for the eight months before being seen by him a tracheal tube. Pains in the neck were severe, and she was unable even to swallow liquids. A tumor was made out in the lower pharynx, but its relations to neighboring parts could not be determined. Examination caused vomiting, in the course of which the patient expectorated a small piece of the mass, which upon examination proved to be a sarcoma with round and fusiform cells. The rapid progress of the growth rendered a laryngectomy necessary, and this was successfully done. A novel form of artificial larynx was inserted, it being worn externally and supplied with air through the tracheal tube.—*Annales des Maladies de l'Oreille, du Larynx, etc.*, January, 1900.

Laryngeal Ictus and Asthma.—Moncorgé gives brief histories of nineteen cases which have come under his personal observation, and refers to similar cases published by others. Special study is made of thirteen cases which came to light upon interrogating three hundred and twenty patients of all ages with reference to this matter. All suffered from some form of cough. Among the three hundred and twenty, Moncorgé found one hundred and thirty-seven cases of true asthma furnishing twelve cases of ictus, while among the one hundred and eighty-three non-asthmatics only a single case of ictus appeared. The author believes that the prolonged congestion of the pharynx and larynx which occurs in asthmatics favors the onset of distinct laryngeal spasm. Moreover, asthmatics are predisposed to all forms of spasmodic seizure.—*Annales des Maladies de l'Oreille, du Larynx, etc.*, February, 1900.

On Malignant Œdema.—Alois Brabec reports the case of a man, twenty-five years old, with malignant œdema. This was clearly a case of sepsis through intoxication, for: (1) a local focus of infection was present; (2) the bacteriological blood findings were negative. (3) A dose of 0.5 c.c. of the œdema fluid could kill a mouse, while 0.1 c.c. had no effect. This is of practical value, for in a septic intoxication only an operative procedure will be effective—in this case exarticulation of the shoulder joint—while in a septic infection surgery seems without result.—*Wiener klinische Rundschau*, March 4, 1900.

The Action of Iron.—Guiseppe Poggi concludes from experimentation that while under normal conditions iron has a hæmoglobinogenetic action, in the pathological conditions created by chlorosis it is first of all a cytogenetic agent, and in some unfavorable cases that alone.—*Rivista Critica di Clinica Medica*, March 3, 1900.

Hemorrhagic Syphiloderma of Adults.—G. Picardi believes: (1) That in addition to the macular, papular, pustular, etc., forms of syphiloderma, there is a secondary hemorrhagic form, characterized by special clinical symptoms and histological structure; (2) that it is exhibited chiefly in situations where there have been previous circulatory disturbances; (3) that it is produced by a process of pericellular and connective-tissue infiltration from the vessels of the derma and subjacent tissue, resulting in extravasation of the blood with all its elements, either from oozing through the degenerated walls or by rupture of the capillaries. —*Il Policlinico*, March 1, 1900.

The Cure of Uterine Prolapse by the Mazzoni Process.—G. Parlavecchio describes this method, which consists in laparotomy, and then in lifting the uterus as high as possible and passing a strong silk thread into the uterine substance at the point of insertion of the round ligament of each side. The peritoneal wound and that of the rectus muscles having been reunited, the two loops of silk which have been brought up through the rectus muscles and their aponeuroses are drawn upon, and each is tied separately. The abdominal opening is then closed.—*La Clinica Ostetrica*, January, 1900.

Treatment of Keratitis Profunda.—Emil Guttmann sums up his ideas concerning this subject as follows: The mercurial treatment, except for small children, is without especial influence and is rather dangerous. Atropine is without influence on the processes in the cornea and should therefore be used as sparingly as possible. Irritating measures should be avoided throughout the inflammatory stage. On the other hand, the systematic application of cocaine as a non-irritating and, indeed, soothing remedy should be followed up, since its use is attended with favorable results in corneal processes.—*Wiener klinische Rundschau*, February 11, 1900.

An Uncommon Manifestation of Cholelithiasis.—P. Grocco calls attention to the cases in which very slight and long-continued fever or feverishness is apparently the only indication of disorder. The spleen is not enlarged, but the liver is usually enlarged and at some point sensitive to pressure. Urobilin is usually present, with polycholia. The author believes that this condition is frequently due to hepatic calculus from infection of the bile passages, and that it may be cured by treatment addressed directly to the liver, even when antiseptic treatment of the intestines has failed.—*Rivista Critica di Clinica Medica*, February 17, 1900.

The Heart in Life Insurance.—According to J. N. Upshur, functional murmurs should lead to a rating of postponement, but not unqualified rejection. Cases with murmur which fail to develop hypertrophy or displacement to the right may be safely taken, so also cases in which there has been an endocarditis in infancy or early childhood, but in which the growth of later years has led to a compensating hypertrophy so that there is no failure of the circulation. On the other hand, no risk is first-class when the sound of the valve fails in clearness or is muffled, because this indicates rigidity and loss of elasticity. Alcohol and tobacco, even though their use has been given up, frequently disqualify a man for insurance.—*Charlotte Medical Journal*, March, 1900.

Still Another Contribution to the Knowledge of Kakke in Sucklings.—Z. Hirota, after giving some statistics on the subject and reporting several cases of kakke, sums up his observations as follows: Sucklings are infected through the mother's milk; the infants suffer from severe symptoms of the disease, not only when the mother is affected by the lightest form, but also at such an early stage that the mother appears to be perfectly free from the affection. It is most important to note that a very constant symptom of kakke in the adult is the indican reaction; this can always be found in the urine of the mother, even when there is no other change from the normal condition.—*Centralblatt für innere Medicin*, March 17, 1900.

Coupling and Redoubling of the Second Sound in Mitral Stenosis.—Luigi Ferrannini says that the double sound heard at the base of the heart is a coupling of the second physiological sound, due to unequal pressure in the large arterial trunks, because of which the aortic semilunar valves do not close simultaneously with the pulmonary. The double sound at the apex is a redoubling because due to the addition of an entirely new sound, and not a part of another sound. The two phenomena are absolutely separate and distinct, and as such cannot be due to the same cause.—*La Riforma Medica*, March 10, 12, and 13, 1900.

Contribution to the Question of Operative Treatment of Neuralgia of the Trigeminal Nerve.—A. B. Tichonowitch, after reviewing various operative measures in the treatment of neuralgia of the trigeminal, states that the method of Quénu and Sebileau is in his opinion the best. It offers a perfectly free entrance to the Gasserian ganglion; the technique of the operation is comparatively simple; the extent of bone resection is limited; the course followed to reach the foramen ovale between the bone and the periosteum is without danger; there are no great vessels to be encountered; the tissues concerned are easily recognizable; the favorable opportunities for ligating the middle meningeal artery, and the rather small dimensions of the opening made in the bone, show this method to be the most advantageous.—*Centralblatt für Chirurgie*, March 24, 1900.

Hypertrophy and Dilatation of the Colon in an Infant.—Lyder Nicolaysen reports the case of an infant who suffered from constipation since shortly after birth, the abdomen becoming gradually distended. The child was sickly, and had frequent attacks of vomiting. When six months old, he presented a deplorable spectacle. The abdomen was enormously distended, measuring 70 cm. in circumference at the umbilicus; from the navel to the symphysis pubis it measured 15 cm., and from the navel to the ensiform process 27 cm. But little effect was produced by enemata, and at the age of twenty-one months the child died from a slight attack of bronchitis. At autopsy the large intestine was found to be greatly enlarged, measuring 26 cm. in circumference, and its walls were exceedingly thin. No obstruction could be found in any part of the intestine. Axel Johannessen reports three similar but less marked cases in the same journal.—*Norsk Magazin for Lægevidenskaben*, March, 1900.

MEDICAL RECORD:

New York, April 28, 1900.

THE DIAGNOSIS OF SMALLPOX.

IN its early stages and in a modified form smallpox presents many points of similarity to various diseases and particularly in the latter form to chicken-pox. Its correct diagnosis is by no means at all times an easy matter, and many physicians among those who have had little or no practical experience in treating the disease, and whose knowledge as to its diagnostic features is chiefly derived from the text-books, are liable to be led astray by its similitude to chicken-pox. As a rule, too, the medical practitioner is conversant only with typical smallpox. When smallpox in a mild form is extremely prevalent, as it is at present in Illinois and many other States, the necessity for medical men to be able to distinguish with unerring accuracy between the above maladies will be clearly understood. Through a mistaken diagnosis an epidemic may be spread far and wide, not only causing much sickness and mortality, but entailing also financial and trade embarrassments of a serious nature.

Public Health Reports, March 23d, publishes a circular sent by the Illinois State board of health to the physicians of that State with regard to varicella in the adult. Among other apropos remarks are the following: "The occurrence of chicken-pox in adults is so rare as to have escaped the observation of many of those who have devoted years to the study of exanthematous diseases. That it does occasionally exist during adult life is not denied, but its appearance at this period is so uncommon as to excite comment. All cases of so-called chicken-pox in adults seen by this board during the present epidemic presented a well-defined variolous eruption." In support of the assertion that chicken-pox rarely attacks other than children, and that an epidemic eruptive disease affecting adults and children alike is not chicken-pox, many quotations from text-books of unquestionable authority are tendered. Dr. John MacCombie, in Allbutt's "Practice of Medicine," says: "A large proportion of cases that occur nowadays in a well-vaccinated community are of the modified form. In many instances so completely is the course of the eruption altered and the symptoms after the initial stage is over are so modified that it is often difficult to recognize the identity of the ordinary and modified diseases. In modified smallpox as a rule the whole of the eruption is out within twelve hours of the appearance of the first papulæ. In ordinary cases it is not abundant and may be macular at first or from the very beginning papular. In either case much of the eruption is vesicular within twelve to twenty-four hours, and the vesicles attain their full growth in about three days, while some of the papules abort without becoming vesicles. In size they are usually smaller than those of natural smallpox, less regularly circular, more conical, and very often not depressed in the centre, although many show a faint line of redness from the beginning. On the third and fourth days of eruption the vesicles are opaque, the lymph is cloudy, and in many patients they do not become pustules, but desiccate unruptured, inspissated lymph forming small brown, flat, and slightly raised prominences about the size of a small sago grain or less under the epidermis. If they do become pustules they attain the size of full pustulation within five or six days of the appearance of the eruption, and thereafter desiccate ruptured or unruptured, as the case may be. The crust or desiccated pustule falls off in the course of a week or less, exposing a flat, reddened, healed surface of epidermis where usually a little desquamation follows." The same author writes: "The diagnosis of chicken-pox must be determined by the distribution of the eruption and the character of the vesicles distributed on the trunk, thighs, and arms. In chicken-pox the eruption is most abundant on the trunk, less so on the face, still less so on the forearms and legs, and least of all on hands and feet. This circumstance attracts attention, and if the eruption be carefully examined, typical unilocular oval vesicles are invariably found on the abdomen, chest, sides of trunk or back, mixed very often with macules, papules, and small abortive vesicles. . . . On the extremities the similarity of the vesicles of chicken-pox to those of modified smallpox usually increases in direct ratio to the distance from the trunk. In many cases the vesicles on the forearms, legs, back of hand, and back and dorsum of foot are round and hard, small in size, not unlike the eruption of modified smallpox. But all cases of chicken-pox present typical vesicles on either the abdomen, chest, back, thighs, or arms."

From the foregoing description it will be gathered that in the case of an eruptive disease resembling smallpox or chicken-pox, if a careful examination be made as to the character and location of the vesicles a correct diagnosis should be arrived at without much difficulty. When, however, an epidemic of smallpox is abroad, all complaints of an eruptive nature should be viewed with suspicion, and if a physician feels in the least doubtful with regard to any particular case it will be better for him to err on the side of caution and to observe strict precautions, than by a mistaken diagnosis perhaps to menace the health and lives of a whole district.

Cocaine Effect upon the eye can be increased by instillation of a watery solution of suprarenal extract.

THE ETIOLOGY OF GENERAL PARALYSIS OF THE INSANE.

The view that both paretic dementia and tabes dorsalis are largely due to syphilis is receiving gradually increasing acceptance, although there are still wide differences of opinion as to the frequency of this etiological relation. In the present state of knowledge it would be a mistake to maintain that this association exists in all cases, and if it is admitted, as it must be, that other causative factors are operative, it can be readily seen that the proportion of each will vary widely, in accordance with numerous conditions. Further, it is scarcely contended that the two diseases of the nervous system named are truly syphilitic disorders, but rather that they are secondary degenerative results of the antecedent infection, and this assumption also renders it probable that other infectious processes may exert a like influence.

An interesting statistical contribution to the literature of this subject is made by Sérieux and Farnarier (*Revue de Médecine*, February 10, 1900, p. 97), who report the results of an analysis of 58 carefully investigated cases of paretic dementia, of which 46 occurred in men and 12 in women. Of this number 16 were rejected because the evidence was inadequate. The remaining 42 were divided into four groups: 1, those in which syphilis had certainly been present; 2, those in which, from the history and the physical signs, syphilis had probably been present; 3, those in which syphilis had probably not been present; and 4, those in which syphilis had certainly not been present. As a result of this analysis it was found that syphilis had been present with certainty in 21 cases, 50 per cent., and with probability in an additional 12 cases—28.6 per cent. Syphilis had probably been absent in 6 cases, 14.3 per cent., and certainly absent in 3 cases—7.1 per cent. Syphilis was found to be the sole etiological factor in 13 cases—31 per cent. Among other etiological factors were found the following: Neuropathic or psychopathic heredity in 14 cases—33.3 per cent.; alcoholism in 8 cases—19.1 per cent.; arthritism in 7 cases—16.7 per cent.; typhoid fever in 7 cases—16.7 per cent.; cranial traumatism in 4 cases—9.5 per cent.; variola in 2 cases—4.8 per cent.; carbon-monoxide poisoning in 1 case—2.4 per cent; furunculosis in 1 case—2.4 per cent.

It thus appears that syphilis is twice as frequent a cause of paretic dementia as typhoid fever, smallpox, and alcohol combined; two and one-half times as frequent a cause as neuropathic or psychopathic heredity, and eight times as frequent a cause as cranial traumatism. Neuropathic or psychopathic heredity is encountered in about one-third of the cases, but this figure is probably too small, as heredity appears to be the basis necessary for the development of general paralysis. The duration of the period of incubation was found to be in the mean fourteen or fifteen years, with six and thirty-two years as the extremes. This period includes the so-called period of invasion, that is, the period during which morbid phenomena are so little marked that restraint is not necessary. This period, so far as can be judged, may have a duration of two or three years, and the true period of incubation is thus reduced to about twelve years. The mean age at which restraint of general paralytics becomes necessary is in the neighborhood of forty years. Deducting fifteen years from the latent period (incubation and invasion), twenty-five years would be about the age of contagion.

Whatever may be the significance of syphilis as a cause of paralysis, it is not the sole cause. The action of syphilis is incidental and not specific, and it appears demonstrated that toxic substances of various kinds—chemical poisons (lead, alcohol), vegetable poisons (diseased rye), microbic poisons (syphilis), and perhaps also agents of auto-intoxication, are capable of causing meningo-encephalitis in predisposed individuals. This disease does not, therefore, merit the designation exclusively of a parasyphilitic or even a parainfectious, but the more general one of a paratoxic affection.

THE RELATIONS BETWEEN THE LYMPHATICS AND THE BLOOD-VESSELS.

It is commonly taught that the lymphatics discharge their contents into the venous system through the thoracic duct on the one hand and the right lymphatic duct on the other hand, at the junction of the jugular and subclavian veins on either side, and by inference it is implied that there is no other communication between the lymphatics and the blood-vessels. There is, however, evidence that such communication exists and perhaps not rarely. A contention to this effect was made by Lippi of Florence in 1825, and more recently MacAllister has also come to the support of the same view. Boddaert demonstrated experimentally in rabbits and by dissection the existence of communication between the lymphatics and the veins. Additional observations of a like character have been recorded by Leaf (*Lancet*, March 3, 1900, p. 606), who in several dissections has observed a communication in the inguinal region in the human subject between the lymphatics and the veins. In one instance the thoracic duct was double. One of the lower left intercostal veins terminated in the lesser azygos vein and was connected by a small communicating branch with the left half of the thoracic duct. In another instance a large lymphatic trunk terminated directly in the greater azygos vein, and an intercostal lymphatic terminated in the lowest intercostal vein on the right. Leaf believes that the communications between these two sets of vessels are not uncommon, and he is inclined to regard them as normal. He has frequently observed that some of the intercostal lymphatics pour their contents into some of the intercostal veins or into one or both azygos veins; or that some large lymphatic trunks in the neighborhood of the receptaculum chyli empty into the greater azygos vein. Sometimes blood apparently passes from a vein into a lymphatic, quickening the sluggish movements of the lymph-current. In some instances a communication was found also to exist between lymphatics and arteries and occasionally between lymphatics and arteries and veins. These facts may help to explain the pink or reddish color sometimes presented by lymph, and also some peculiarities connected with the dissemination of sarcoma and carcinoma. Thus, sarcoma, while usually spread by the veins, sometimes invades the lymphatic glands, and carcinoma, while usually invading the lymphatic glands, is sometimes spread by the veins.

News of the Week.

A Bureau of Materia Medica.—At the annual meeting of the Medical Society of the State of New York in January, a resolution was adopted to the effect that the interests of medical science require the establishment of a bureau of materia medica in order to institute disinterested investigation into the character and value of new drugs. And the society recommended to the Decennial Convention of 1900 for the revision of the United States Pharmacopœia, the creation of such a bureau by and under its authority, with the provision that it shall report annually upon the matters coming properly within the scope of its work.

An Impostor.—A medium-sized, corpulent man, dressed as a laborer, is visiting certain physicians with the statement that they have been proposed as lodge physicians. He is armed with a letter of introduction, obtained by false representation, from one reputable practitioner to another. Professing that neither of these physicians, for various reasons, can take the position, he offers it to his intended victim, from whom he asks for from $3 to $5 as a proposition fee to be forwarded to the physician-in-chief.

The New York Genito-Urinary Society.—A new medical society has been formed under this name, the membership in which will be confined to medical men engaged in active clinical work in connection with one branch or another of this specialty. Meetings will be held once a month, when cases will be reported, and at least one paper read. The officers for the first year are: *President*, Dr. Ramon Guitéras; *First Vice-President*, Dr. Winfield Ayres; *Second Vice-President*, Dr. Otis K. Newell; *Treasurer*, Dr. George W. Blanchard; *Secretary*, Dr. A. D. Mabie; *Corresponding Secretary and Stenographer*, Mr. Samuel Bennett, 161 Garfield Place, Brooklyn. The corresponding secretary will furnish information as to terms of membership, etc.

The Fourth International Congress of Dermatology and Syphilography will be held in Paris at the Hospital St. Louis, August 2d–9th. The subjects for discussion are: Dermatology: The parasitic origin of eczema (reporters, Kaposi, Unna, Jadassohn, Galloway, Brocq, assisted by Bodin and Veillon); the tuberculides (reporters, Boeck, Colcott Fox, Campana, G. Riehl, J. Dairer); the "pelades" (reporters, Malcom Morris, Lassar, Mibelli, Parloff, Sabourand); the leukoplakias (reporters, Behrend, Springle, Perrin). Syphilography and venereology: Syphilis and associated infections (reporters, Neisser, Bulkley, Ducrey, Hallopeau); the descendants of hereditary syphilitics (reporters, J. Hutchinson, Tarnowsky, Finger, Jullien); causes of generalized blennorrhagic infections (reporters, W. R. Taylor, Lesser, Tommasoli, Lane, Balzer). Those desiring to become members of the Congress should address Dr. G. Thibierges, 7 Rue de Surène, Paris, or the secretary for the United States, Dr. George T. Elliot, 36 East Thirty-fifth Street, New York. The membership fee is $5.

The Ohio State Medical Society.—The fifty-fifth annual meeting of this society will be held in Columbus on May 9th–11th, under the presidency of Dr. Rufus B. Hall, of Cincinnati.

Bequests to Hospitals.—By the will of the late George W. Miles, of Philadelphia, contingent bequests were made to the following institutions: Episcopal Hospital, St. Joseph's Hospital, Presbyterian Hospital, each $8,000; Maternity Hospital, Pennsylvania Hospital, Children's Hospital, Methodist Episcopal Hospital, Germantown Dispensary, Protestant Episcopal City Mission for the Home for Consumptives, Hahnemann College and Hospital, to each $5,000.

Philadelphia Neurological Society.—At a stated meeting held April 23d, Dr. F. Savary Pearce presented a case of peripheral facial palsy, with crossed hemiparesis. The patient was a colored man, who after exposure to cold developed disease of the middle ear and facial palsy on the left side, and some months later, with partial loss of consciousness, developed weakness upon the right side of the body, probably in consequence of hemorrhage into the left cerebral hemisphere. Dr. W. G. Shallcross presented a case of acromegaly, and also a case possibly of acromegaly in an early stage. Both patients were young men, deficient mentally, and inmates of the Pennsylvania Institution for Feeble-minded children. Dr. C. W. Burr exhibited a case of treadler's palsy occurring in an elderly man whose work compelled him to raise and depress many hundreds of times daily a treadle weighing nearly thirty pounds, and who thus developed an occupation neurosis. Dr. A. A. Eshner referred to an analogous condition observed in a motorman and resulting from the manipulation of a gong with the foot. Dr. Charles S. Potts exhibited a case of amyotrophic lateral sclerosis occurring in a man who had been employed in lead works, but who presented no blue line on the gums or other symptoms of lead poisoning. The nervous symptoms predominated on the right side, and were in part bulbar and in part spinal. Dr. C. W. Burr reported a case of general anæsthesia involving both general and special sensibility, only a slight degree of hearing being retained, while the motor sphere was unaffected, except indirectly through the sensory disturbance. The possibility of meningitis was suggested, as there had been acute attacks earlier in life that seemed to be of this nature. Dr. J. Hendrie Lloyd exhibited a specimen of large subdural hemorrhage over the motor region, causing hemiplegia and aphasia, derived from a case that during life suggested only intracerebral hemorrhage, and he referred to another case in which during life the condition was thought, from the symptoms, to be one of subdural hemorrhage, while after death no lesion whatever was found in the brain, and the symptoms were necessarily attributed to uræmia. Dr. F. X. Dercum reported a case of rhizomelic spondylosis. Dr. W. G. Spiller exhibited the brain from a case of hydrocephalus. The patient was an elderly woman, with enlargement of the head from birth, with a history of convulsions, but without paralysis, and with fair intelligence. The ventricles of the brain were greatly dilated and the cerebral structure was extremely attenuated, with adhesions between the occipital lobe of the brain and the cerebellum.

Dr. Josef Gruber, professor of otology at the University of Vienna, died on March 31st, at the age of seventy-three years.

The Administration of Solid Food to Infants under one year of age is forbidden by law in France, except it be upon the prescription of a legally qualified physician.

American Gynecological Society.—The twenty-fifth annual meeting of this society will be held in the lecture hall of the Columbian University, Washington, on May 1st–3d, under the presidency of Dr. George J. Engelmann, of Boston.

Dr. Robert Abbe Consulting Surgeon to Roosevelt Hospital.—At a meeting of the board of managers of Roosevelt Hospital held this week, Dr. Robert Abbe was unanimously elected consulting surgeon to the hospital in place of Dr. Robert F. Weir, transferred to the staff of attending surgeons. We congratulate Dr. Abbe on this well-merited honor.

American Neurological Association.—The twenty-sixth annual meeting of this society will be held in Washington, in conjunction with the Congress of American Physicians and Surgeons, on May 1st–3d, under the presidency of Dr. Edward D. Fisher, of New York. The sessions will be held at The Normandie.

Dr. Jacobi's Seventieth Birthday.—A number of the friends and professional associates of Dr. A. Jacobi, of this city, have constituted themselves a general committee for the purpose of arranging for the proper celebration of the seventieth birthday of Dr. Jacobi, in May. Under the auspices of the committee, a complimentary subscription dinner will be tendered Dr. Jacobi, at Delmonico's, Forty-fourth Street and Fifth Avenue, on Saturday, May 5th, in which the physicians of the city are invited to participate. The price of the dinner will be $10, including wine. An application blank may be had by addressing Dr. A. G. Gerster, P. O. Box 3,032, New York City.

The Hospital Ship "Missouri" is to be converted into a transport, having been found unsuitable for a hospital ship without very extensive alterations. The sick and wounded will hereafter be brought from the Philippines in the ordinary transports, sailing every two weeks. The *Missouri* was fitted out as a hospital ship at New York at great expense several months ago, and has since made a trip from this port to Manila, and thence to San Francisco. On the second half of the voyage she carried a large number of sick and wounded soldiers. Throughout the entire voyage there was constant friction between the medical officer in charge and the master and other officers of the vessel. Soon after her arrival at San Francisco the charges made by the officers against each other were officially investigated, with the result that the surgeon was sustained and the civilian officers were dismissed from the transport service.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 21, 1900: April 13th.—Medical Inspector G. E. H. Harmon detached from the *Baltimore* and ordered to the *Oregon*. Surgeon F. B. Stephenson detached from the *Oregon* and ordered to the *Baltimore*. April 16th (changes by cable from Asiatic station).—Passed Assistant Surgeon L. Morris to the *Baltimore*. April 17th.—Passed Assistant Surgeon S. G. Evans, order of April 13th modified; ordered to proceed home when detached from the *Marblehead* and to be ready for sea duty.

The Dry Tortugas Quarantine Station.—A controversy between the Treasury and Navy departments over the retention of the Marine-Hospital station on the island of Dry Tortugas, forty miles west of Key West, has been settled by the agreement of the Navy department to issue an order permitting the quarantine station to remain where it is until the expiration of the quarantine season against ships from Cuba next autumn. The authority of the Navy department was recently extended over Dry Tortugas, and the Marine-Hospital service, which has used the place for a quarantine station for many years, was directed to vacate.

Proposed Taxation of Medical Practitioners in Turkey.—According to the *Moniteur Oriental* the Turkish government has hit upon an ingenious device for checking unqualified practice and at the same time levying a tax on the legitimate practitioner. It is proposed to make the use of prescription books bearing a government stamp compulsory on all medical practitioners. It is estimated that this would yield to the treasury a revenue of 300,000 or 400,000 piastres a year, while quacks would be hindered in their depredations by the fact that in each prescription book the name of the doctor using it and the number of his diploma must be inscribed. The proposal has been referred to the directing committee of military schools. Similar plans have been suggested more than once before, and have been rejected, and it is thought unlikely that the present proposal will be more successful.—*The British Medical Journal.*

The Plague.—The deaths from the bubonic plague in India during the week ending April 18th aggregated more than 4,000, which is slightly less than in the preceding week.—The disease appeared some three weeks ago in the Javanrood district in Persia, near the Turkish border, 200 deaths having occurred. Cases have also been reported in several places on the Red Sea.—A despatch from Manila, dated April 21st, states that a number of sudden deaths of Filipinos and Chinamen in Quiapo Market have led to an investigation, showing that fifteen cases of the plague, fourteen of which were fatal, have occurred within a week. The market is located in the centre of the city. Some of the plague victims were stricken and died within an hour. After all the market people had assembled the health officers threw a guard around the buildings and will keep the inmates quarantined there for a fortnight. They will then burn the market. The plague elsewhere in the city has been suppressed, not a single case having been reported from the Chinese district for ten days. The total number of deaths is 185—119 Chinamen and 66 Filipinos.

Women in the Boer Army.—It is said that a number of women in male attire have been discovered among the captured Boers and among the dead on the battlefield.

The Famine in India is reported to be steadily increasing, especially in the districts of Bombay and Rajputana. Five and a half millions of people are now on the relief lists.

The Hospital Ship "Maine" has arrived at Southampton with many wounded soldiers from South Africa. The patients were taken to Netley, and the ship will return to the Cape as speedily as possible.

Treatment of Tetanus in the French Army.—By a recent order of the French army medical service medical officers are directed to use injections of antitetanus serum in large and repeated doses in all cases of pronounced tetanus. In justification of the order is a statement that experience has shown that such injections have a favorable effect in many cases.

A Case of Counter Prescribing.—A man went into a Bowery drug-store last Sunday and asked for something to relieve a headache. The clerk, for some unexplained reason, gave him a bottle of tincture of larkspur. The man with a headache took a tablespoonful of the tincture, and was next heard of in the hospital with gastritis.

A Large Gift to Mt. Sinai Hospital.—A gift of $200,000 has been made to Mt. Sinai for the purpose of erecting the pavilion for private patients on the new site at Fifth Avenue and One Hundredth Street. The money is given by Mr. Meyer Guggenheim and his seven sons in memory of their deceased wife and mother. This gift leaves only about $400,000 still to be raised in order to erect all of the nine buildings constituting the new hospital.

Stealing the Livery of Heaven.—The United States consul at Pretoria has informed the State department that members of the ambulance corps sent from Chicago and other places by American sympathizers with the Boers to attend the Boer sick and wounded have taken up arms against the British. The State department will probably complain to the Transvaal government against permitting these American citizens to serve in the Boer army, on the ground that they were permitted to leave the United States with the understanding that they were to serve as neutrals in humane work. All these men took an oath, before leaving this country, that they would not join the combatants on either side, and it was on this representation and because of the indorsement of Miss Clara Barton that they were permitted by the Portuguese authorities to pass through the Delagoa Bay territory. Dr. MacNamara, one of the physicians who went with the corps from Chicago, is reported to be at Lourenço Marquez on his return home, disgusted with the treachery of his companions. Despite this abuse of the Red Cross name, it is reported from Chicago that another ambulance corps will be fitted out and sent to the scene of war. The promoters are now working hard, and an expedition of fifty men, it is said, will be sent to the Transvaal, fully equipped, within a month. According to a despatch to *The Daily Mail*, of London, these are not the only men who have gone to the Transvaal under the pretence of healing wounds and then have set out to inflict them, for all the ambulance corps which have been sent from the continent of Europe have repudiated the Red Cross as soon as they reached Pretoria.

The Death Rate in Philadelphia continues unusually high. For the week ending April 21st there were reported to the bureau of health 739 deaths, 48 more than for the preceding week, and 294 more than for the corresponding week of the previous year. Not less than 123 of these deaths were due to pneumonia (and 10 besides are attributed to congestion of the lungs and 5 to pleurisy); 84 deaths resulted from pulmonary tuberculosis, 56 from disease of the heart, 36 from nephritis (together with 23 attributed to uræmia), 34 from convulsions, 31 from influenza, 25 from apoplexy, 24 from measles, 21 from inflammation of stomach and bowels and senility each.

College of Physicians of Philadelphia.—At a special meeting held in conjunction with the Philadelphia Neurological Society on April 20th, a discussion was held on "The Fifth Nerve in its Neurological and Cervical Aspects," and the following papers were read: "Peripheral Resection of the Fifth Nerve," by Dr. W. W. Keen and Dr. W. G. Spiller. "Pathological Report on Two of the Gasserian Ganglia Removed by Dr. Cushing," by Dr. W. G. Spiller. "Microscopic Studies of Gasserian Ganglia," by Dr. L. F. Barker, of Baltimore. "The Natural History of Tic Douloureux, with Some Observations on Treatment," by Dr. C. L. Dana, of New York. "On a Method of Total Extirpation of the Gasserian Ganglion by an Infra-Meningeal Route, through the Temporal Fossa, with a Report of Four Cases," by Dr. H. W. Cushing, of Baltimore. "Method of Exposing the Gasserian Ganglion; Removal of the Superior Maxillary Nerve," by Dr. G. G. Davis. "Endothelioma of the Gasserian Ganglion; Two Successive Resections of the Ganglion: First, by the Extradural (Hartley-Krause) Operation; and, secondly, by an Intradural Operation." Clinical Report by Dr. F. X. Dercum; Surgical Report by Dr. W. W. Keen; Pathological Report by Dr. W. G. Spiller. "Contribution to the Surgery of the Fifth

Nerve," by Dr. Robert Abbe, of New York. "Contribution to the Surgery of the Fifth Nerve," by Dr. L. McL. Tiffany, of Baltimore.

Obituary Notes.—DR. JOHN JOSEPH CRANE, of this city, died on April 18th, at the age of forty-nine years. He was born in Elizabeth, N. J., and was a graduate in arts of Princeton in 1873, and in medicine of the College of Physicians and Surgeons, New York, in 1876. Upon receiving his degree he became the resident physician of Roosevelt Hospital. From Roosevelt Hospital he went to Elgin, Ill., and became the first assistant physician in the insane asylum there. He remained in Elgin for several years, and then returned to this city and entered upon practice.

DR. EDWARD FRANK GRANT died from smallpox on his coffee plantation near Mettalalteyuca, Pueblo, Mexico, on April 5th, at the age of forty-five years. He was a native of this State, but soon after graduation went to Lodi, Cal., and later purchased a plantation in Mexico. The disease which killed him was contracted while visiting a peon living on a neighboring ranch.

DR. JOHN HABIRSHAW died at his home in this city on April 20th, at the age of forty-six years. He was a graduate of the College of Physicians and Surgeons in 1877.

DR. ALVIN B. ALLYN, a homœopathic physician of Chardon, Ohio, died in Cleveland on April 20th of injuries received by being shut up in a folding bed. He had been under treatment for some time for nervous prostration. He was a graduate of the medical department of the University of Michigan in 1879.

DR. WILLIAM F. ROBINSON died at Philadelphia on April 15th at the age of sixty-three years. He was born in Boston, but was educated in the schools of Philadelphia, being graduated from the medical department of the University of Pennsylvania. He practised medicine for ten years in Hatboro, Montgomery County, and in 1873 established the *Hatboro Free Spirit*, of which he was the editor until his death. He was for six years State quarantine physician at the lazaretto, and for eight years connected with the bureau of health. For four years he was surgeon to the Bucks County regiment, the One Hundred and Fourth Pennsylvania volunteers.

Night Sweats.—In the hyperidrosis of phthisis we may employ white agaric in dose of 0.25 to 0.30 cgm.; sulphate of atropine, one or three granules each containing a quarter of a milligram, at intervals of two hours during the evening. Ergot is also used. Camphoric acid in cachets of 1 gm., two or three times a day; tribasic phosphate of lime 4 gm. in two doses a half-hour apart in the middle of the day; tannin in doses of 0.30 to 0.50 cgm.; zinc oxide same dose; fluid extract of hydrastis canadensis, gtt. xxx. at bedtime. Best of all is the tellurate of sodium. It should be prescribed in average daily dose of from 2½ to 3 cgm. for three or four days consecutively. A daily quantity of 5 cgm. should not be exceeded. It may be given in alcoholic solution or preferably in pill form.—ERNEST BARIÉ, *Journal des Praticiens*, February 17th.

Progress of Medical Science.

The Boston Med. and Surg. Journal, April 19, 1900.

Treatment of Cancer of the Cervix of the Uterus Complicated by Pregnancy.—George Ben Johnston says that when the cancer appears before the termination of the fourth month of pregnancy and is limited to the cervix, the sole consideration must be the welfare of the mother, and hysterectomy must be performed, usually per vaginam. When the disease has extended to the vagina and possibly neighboring structures, rendering the condition inoperable, the efforts should be entirely in behalf of the child; the mother must be sustained until the end of term if possible, or until the child is viable. Delivery by the natural channel is fraught with such formidable dangers—laceration, hemorrhage, infection with peritonitis—that Cæsarean section should always be resorted to as less perilous. When the disease is discovered after the fourth month and remains limited to the cervix, immediate ablation of the uterus is demanded if the disease is progressing with rapidity; if slowly, postponement until the completion of the seventh month or later, when a Cæsarean section may save both mother and child, is to be advised.

Intermenstrual Dysmenorrhœa.—Malcolm Storer reports twenty cases of pain which appeared with regularity usually from the twelfth to the sixteenth day after the beginning of the last menstruation, lasting from two to four days, paroxysmal in character, or constant with exacerbation. There was no menstrual discharge, but leucorrhœa. The author offers the following theory in explanation of the phenomenon: The intermenstrual pain coming about the fourteenth day from the beginning of menstruation, the nineteenth after the climax of Stephenson's wave, occurs just about the time the pressure line has reached its lowest point. Cannot then the intermenstrual wave, if one exists, be one of preparation rather than of subsidence, a nervous explosion, so to say, as if nature were waking up with a more or less violent effort to make ready for the coming activity, whether menstrual or ovarian?

A Hair Ball in the Stomach.—John Homans describes a case in which a mass of hair, nine inches long by two and a half inches wide, was removed from the stomach of a young woman who had for twelve years swallowed the hair combings. The patient recovered. This was in London, in 1866.

The Practical Value of the White Blood Count in Surgical Cases.—J. C. Hubbard says that from our present knowledge of the causes and variations of leucocytosis we cannot yet make any deductions which are simple enough to be of any great use to the surgeon at the bedside.

Third International Congress of Obstetrics and Gynæcology Held at Amsterdam.—By George J. Engelmann.

Gunshot Wounds of the Abdomen, with Multiple Wounds of the Intestines.—By Howard A. Lothrop.

Journal of the American Med. Ass'n, April 21, 1900.

Affections of the Kidney in Relation to Pregnancy.—J. Clarence Webster reviews different theories regarding the changes in the kidneys during pregnancy, advanced by the principal workers in this difficult field, and says it must be admitted that much is to be said in favor of each; that it is probable that something of the truth is contained in all of them, and that in most cases no single factor is causal, but rather a combination of various factors, these varying greatly in different cases. The most important of these is undoubtedly the toxic element. As to treatment, the writer says it is to be carried out on lines followed in the non-pregnant state. The strictest watchfulness on the part of the physician is necessary. As to the question whether the pregnancy shall continue, it is difficult to decide. Certain symptoms, however, point imperatively to the induction of premature delivery, in the interests of the mother, viz., visual disturbances and continued headache, pulmonary or other marked œdema, marked cardiac disturbance, frequent nose-bleedings, continued increase in the casts and albumin in the urine, and uræmia.

Castor Oil in the Treatment of Neuralgia.—Harold M. Moyer reports several cases of neuralgia which he has treated with castor oil with good results. The results with acute neuralgias were, as might be expected, better than with the chronic, although even in the latter only one failure is recorded, when a patient with a neuralgia of the third division of the nerve on one side continued the treatment for two or three weeks with no improvement in the symptoms. The oil is administered in the morning before breakfast, and the dose is from one to two ounces. The most efficient means of administration is in ale, preferably Dogshead or Bass', which contains a large quantity of gas. When first given it acts freely on the bowels, but if continued daily its cathartic effect rapidly diminishes. The author does not think that the value of this oil in neuralgias is due to its cathartic properties, but thinks it probable that substances are present in it which have not been fully identified, which substances may have some effect on the sensory nerves.

Thyroid Extract in Juvenile Obesity.—I. N. Love reports four cases of juvenile obesity which he has treated with the thyroid extract, especially that of a boy, aged eight years, who weighed before treatment one hundred and thirty-one pounds. In connection with proper purgation, diet, and exercise he was ordered one-half of a five-grain tablet of thyroid extract three times a day, with a gradual increase until one tablet was taken four times a day. After fourteen months' treatment this boy now weighs one hundred and six pounds, the chief feature of his case being that he has developed muscle to a considerable degree. The writer has found strychnine, in doses ranging from gr. $\frac{1}{150}$ to gr. $\frac{1}{50}$, a most excellent drug to be taken with the thyroid in order to prevent depression and unpleasant effects.

Primary Tuberculosis of the Kidney.—In this case, reported by Dudley Tait, lumbar nephrectomy was performed with subsequent total resection of the ureter, followed by complete recovery. The points of interest in the case are: (1) The perirenal tuberculous infiltration, a rare and troublesome condition, complicating both the operation and the subsequent treatment; (2) the absence of vesical lesions, causing this case to be a strong evidence in favor of the reflex theory advanced by Le Dentu and most of the English authors, Newman, Roberts, and Morris.

Cerebral Cyst.—This case is reported by Van Buren Knott to illustrate the following point: Every operation on the brain must be considered as largely exploratory, and promises of a definite result cannot be made. Nevertheless, such operations properly performed will do no harm, and whenever in any given case the symptoms point to a lesion, the localization of which seems probable, the patient should be given the chance of relief which may follow a properly conducted operation.

Medical News, April 21, 1900.

Pain as a Pathognomonic Symptom of Ectopic Pregnancy.—Henry C. Coe, after citing several cases, concludes that pain alone, when not accompanied by a clear history of menstrual irregularity, symptoms of pregnancy, and the presence of a tumor at the side of the uterus or in Douglas' pouch, known to be of recent development, is pathognomonic of extra-uterine pregnancy only under certain conditions, viz., the pain is of a sharp colicky character, distinctly localized on one side, attended with faintness more or less marked, and is usually followed by intervals of hours or days of complete remission. The pulse is accelerated, but there is no rise of temperature as in inflammatory conditions.

Tuberculous Disease of the Urinary Apparatus.—J. M. Gile states that this condition is of considerable frequency. Its course is as variable as that of the same disease when affecting other organs, and may prove rapidly fatal or run an indolent course. For certain diagnosis we must depend on the bacteriologist, but even this will not definitely localize the trouble. The hereditary character is more marked than in pulmonary tuberculosis. The age incidence, from the writer's cases, is markedly in young adult life rather than in middle age, while the location is merely a matter of circumstance.

Philadelphia Medical Journal, April 21, 1900.

Appendicular Abscess Rupturing into the Sac of a Reducible Inguinal Hernia.—Orville Horwitz reports this case in which the sac was opened and drained, the result being a permanent cure of the hernia. The same writer reports a case of intussusception of the bowel which was relieved by operation: a relapse occurred, another operation was performed, and the patient died three days later. A third case was one of chronic hæmatocele of the tunica vaginalis testis, associated with an encysted omental hernia, resembling malignant disease of the testicle.

Early Operation in Appendicitis by the Country Practitioner.—R. H. Harper reports a case of appendicitis in a boy, aged thirteen years, who had just recovered from an attack of typhoid fever. The operation was performed with the child on a kitchen table; the assistants were two women and a man; the towels and instruments were sterilized with boiling water. By an oversight the silk was not sterilized, and there were stitch-abscesses along the upper half of the incision, but with this exception the result was all that could be desired.

Infection through the Tonsils, Especially in Connection with Acute Articular Rheumatism.—By Frederick A. Packard.

Two Cases of Fracture of the Shaft of the Radius.—By W. B. Lowman.

Selections from the Lane Lectures.—By T. Clifford Allbutt.

New York Medical Journal, April 21, 1900.

Cancer of the Stomach in the Young.—W. Osler and T. McCrae collate the records of cases of this nature, dividing them into classes based on the first three decades of life. Six cases only are on record below ten years. Thirteen are recorded during the second decade. The authors record six additional cases occurring between the ages of twenty and thirty. An analysis of the various symptoms is given, and the article closes with the following conclusions quoted from Mathieu: (1) Cancer of the stomach below the age of thirty has generally a rapid progress in some months, and often ends suddenly by incidents more or less abrupt. (2) Early cancer is not latent; it is often overlooked.

A Consideration of the Neuro-Muscular Elements in Hip-Joint Disease, with Especial Reference to the Question of the Abolition of Protective Treatment.—By N. M. Shaffer.

Hepatic Abscess.—J. F. Richardson reports a case in a man aged twenty-four years. The abscess ruptured into a bronchus, but the patient eventually recovered.

Some Practical Remarks on Clinical Examination of the Blood.—By W. N. Berkeley.

Mysticism among the Negroes.—By F. J. Carroll.

British Medical Journal, April 14, 1900.

Amputation without Anæsthesia.—D. Mackinder reports the case of a delicate woman of the pallid, nervous temperament who objected to chloroform and submitted to an amputation of the breast without an anæsthetic of any sort. She did not make a sound, but simply compressed her lips, and said "Thank you!" when all was over. Another case was that of a large, athletic man whose finger was amputated in consequence of an injury. He refused to take an anæsthetic, and kept laughing and joking throughout the operation. J. Campbell Hall also reports the case of a large, stout woman, seventy years of age, whose right leg was amputated above the knee for gangrene some twenty years ago. She took no anæsthetic then. Recently gangrene appeared in the left leg, and amputation between the lower and middle thirds of the thigh was performed, this time also without anæsthesia, the patient never uttering a sound or moving in the least. She made an excellent recovery.

The Seat of Pain in Biliary Colic.—J. H. Keay says that, from a distressing personal experience and from observation of other sufferers, he is convinced that the usual description of the pain given in the text-books is incorrect. In his own case, he says, long before an acute attack there are pains in the back, often mistaken for lumbago, but when the calculus is fairly lodged in the duct, the pain begins about the tenth or eleventh dorsal vertebra, and gradually passes round, giving place to excruciating pains in the right and often the left hypochondrium, middle or lower abdomen, frequently above the right nipple, but practically never in the right shoulder. Immediately before the pain subsides, when probably the stone is just entering the duodenum, a peculiar gliding sensation is sometimes felt about two inches to the right of the tenth or twelfth dorsal vertebra.

Non-Diabetic Glycosuria.—Robert Saundby discusses the various conditions under which sugar may appear in the urine in the absence of true diabetes mellitus. In examining for sugar, if the copper is reduced on the first test, he makes sure that it is sugar and not some other reducing agent (such as glycuronic acid, chloral, etc.) by filtering the urine seven or eight times through animal charcoal. This removes all of the reducing agents except sugar. The various forms of non-diabetic glycosuria which he reviews are alimentary or physiological, alcoholic, hepatic (many of which are really alcoholic), gastric, neurasthenic, and senile.

Some Cirrhoses of the Liver.—By W. B. Cheadle.

Diphtherial Stomatitis.—By E. F. Trevelyan.

The Lancet, April 14, 1900.

Some Cirrhoses of the Liver.—In this lecture W. B. Cheadle considers the subject of treatment. Absolute abstention from alcohol and all stimulating ingesta is the first requisite. Diet should be restricted to milk, eggs, simple proteids, bread, and fresh fruit and vegetables. Predigested foods are necessary in some instances. Mild laxatives, together with iron or other tonics, are all of service. Mercury and the iodides are indicated, of course, in syphilitic cases, and, owing to the possibility of diagnostic error, should be tried even in the alcoholic cases. When there is cardiac weakness, digitalis will give us the best results. For the ascites diuretics and tapping are advised, but after the latter is done the patients should be kept under close observation for a long period.

The Typhoid Bacillus and Typhoid Fever.—P. Horton-Smith devotes this lecture to a consideration of the Widal test, speaking of its discovery, technique, nature of the agglutinating substance, limitations of the test, etc. He considers the agglutins to belong to the ferment class. Under the head of treatment, he considers preventive inoculation, and highly extols the use of urotropin, which practically does away with the danger of spreading infection by means of the urine. Results of certain bacteriological experiments are given to prove the claims made in this direction.

A Case of Spontaneous Rupture of the Heart and Hemorrhage into the Pons Varolii.—P. T. Goodman reports this condition occurring in a woman who had indulged in spirits, though not addicted to their use. She complained of loss of power on the right side, and became comatose, dying in five hours. Rupture was found on the anterior surface of the left ventricle, with hemorrhage in the left pons.

Deutsche medicinische Wochenschrift, April 5, 1900.

Two Practically Important Cases of Hysteria.—The first of the cases reported under this title by Ernst Fuerst was that of a woman thirty-six years old, who had suffered for several weeks from vomiting and pains simulating those due to an impacted gall-stone. The case was diagnosed as one of hysteria, but in order to relieve the bilious vomiting it was decided to wash out the stomach. The sound seemed to enter readily, but no fluid could be made to pass through it, and all attempts to withdraw it were unavailing, as it was firmly held by a spasmodic stricture of the œsophagus. It was only when the patient was profoundly narcotized that the tube could be drawn out. Under careful treatment the patient fully recovered. The second case was that of a man who had suffered a fracture of two ribs and who subsequently presented symptoms leading to a suspicion of tuberculosis. The tuberculin test was applied several times, and each time a characteristic febrile reaction followed. Hysteria being suspected, an injection of water was made and the same reaction was produced, and then a simple puncture with the needle of the syringe was made in the back, but not a drop of fluid was expressed, yet the reaction followed as before.

The Serum Diagnosis of Tuberculosis.—Ernst Bendix has applied the agglutination test in thirty-six cases of tuberculosis and obtained the reaction in all but two. Various dilutions were employed, in one case as high as 1 : 50. In both the cases in which the reaction failed the disease was far advanced, and in one of those there was even a minus value, the serum reducing the agglutination power when added to other agglutinating sera, there seeming to be an "anti-agglutinin" in this patient's blood. If one might reason from two cases only, it would seem as though the Gruber-Widal serum reaction was not only of diagnostic value in tuberculosis, but that one might draw certain conclusions regarding the course of the disease; that is to say, that a serum of high agglutination value would indicate in general the presence of a less active tuberculous process than one of less power.

Two Cases of Syphilis with Peculiar Features.—The first of the cases reported by Heinrich Köbner was that of a healthy-looking man, who had a sharply circumscribed, round, slightly raised, bluish, hard infiltration on the anterior surface of the thigh. A scar was visible in its centre. The patient said he had had a boil which was incised. The femoral and inguinal glands were enlarged. There was a very painful, soft, elastic periostosis on the right parietal bone. No eruption was visible. The diagnosis of syphilis was disputed, but subsequent events proved its correctness. Infection had been occasioned probably by the scalpel used in incising the furuncle. The second case was one of constitutional syphilis following a non-indurated initial lesion, which had been diagnosed and treated as a soft chancre.

Syphilis of the Lingual Tonsil and its Relation to Smooth Atrophy of the Follicular Glands of the Tongue.—By W. Lublinski.

Agglutination of the Red Blood Corpuscles.—By G. M. Malkoff.

Treatment of Uterine Hemorrhages.—By H. Ostermann.

Berliner klinische Wochenschrift, April 2, 1900.

Experimental Contribution upon the Effect and After-Effect of the Thyroid Poison.—M. Porges calls attention to a peculiar form of glycosuria which may follow the administration of the thyroid preparations and which is followed by disturbances in the carbonic-acid metabolism. Experiments were made by feeding the thyroid substance to a dog together with other diet, the bodily excreta being carefully estimated before, during, and after the thyroid feeding. From his experience with animals Porges believes that there is a very great variation in susceptibility to the effects of the thyroid extract, and that this accounts for the conflicting results obtained with it as a therapeutic agent.

A New Method of Employing the Silver Compounds in Histology.—Salge and Stoeltzer claim that staining-results in histological technics can be made far more striking if with the use of the silver preparations there is introduced the employment of that class of substances which in photography are called developers. Their method, the description of which must be read in the original, is in brief to immerse the specimen in a silver solution and then transfer it to the "developer," and they enumerate the various solutions which have served them for this purpose in good stead.

The Pyogenic Origin of Chorea Rheumatica and of Rheumatic Processes.—S. Mircoli believes that many cases of rheumatism are directly referable to streptococci, while others may be ascribed to staphylococci, diplococci, and gonococci. In seventeen cases of chorea which he has studied the infection was referable to the staphylococcus in fourteen and to the diplococcus lanceolatus in three. From animal experimentation he finds the same effects upon the heart and serous membranes as are afforded by clinical rheumatic manifestations.

The Treatment of Tuberculosis in the Nineteenth Century.—By Bäumler.

Wiener klinische Rundschau, March 25, 1900.

Psychical Deafness.—Ferdinand Alt, in the beginning of his article, mentions the fact that the term "psychological deafness" was first used by Heller (who is not a physician, but a pedagogue) to designate a condition of seeming deaf-mutism in weak-minded subjects or idiots, that may, however, be cured in many instances. Alt takes exception to the promiscuous use of the term, demonstrating that, for instance, the loss of intellectual perception of sound is by no means identical with psychical deafness. He tries to establish certain points of differentiation and generalization on the basis of the various phenomena observed in connection with this subject.

The Treatment of Eczema in Childhood.—J. H. Rille gives a very extensive description of the most important methods of treatment to be employed in the various types of this disease. In children he has found the use of salicylic-lanolin salve, one-half to one per cent., to be most efficient and reliable. With reference to prophylaxis, he states that vaccination should be omitted, if possible, in patients with eczema, especially if the latter be present on the face, as cases of generalized vaccine, leaving numerous disfiguring marks, have been observed as a result of vaccination.

Wiener klinische Wochenchrift, March 29, 1900.

The Hæmamœba of Löwit in the Blood of Leukæmics.—Wilhelm Türk in a "preliminary report" refers to the demonstration by Löwit at the last Congress for Internal Medicine at Karlsbad, of preparations of the "hæmamœba leukæmiæ magna," and declares that these protozoa do not represent parasitic formations, but so-called "mast-cell granulations." He calls special attention to the fact that Löwit in his experiments with rabbits did not succeed in producing the anatomical and histological picture of a leukæmia, but bases his claim of having transferred the disease to rabbits upon the presence of a chronic recurrent leucocytosis and the authenticity of his hæmamœba. Recognizing the statement above made, that Löwit's "amœbæ" are not parasites, his argumentation would, of course, be without ground, for a chronic recurrent leucocytosis is not identical with leukæmia.

Contribution to the Knowledge of the Semeiotics of the Secondary Pulmonary Sound.—Adolf Hecht gives a very extensive account of his experiments with Bettelheim-Gärtner's stetho-phonometer. He found this instrument to be especially useful in determining the relative strength of cardiac tones, and considers the relation of the second pulmonary to the second aortic tone of greatest value. While he believes that one single examination can be of but little utility, he is convinced that systematic observation enables us to draw important conclusions as to the course of circulatory, respiratory, or abdominal diseases. He also claims that exact physiological studies regarding changes in the lesser circulation are possible, and that many of the facts obtained as a result of experimental research may thus be confirmed in the human subject.

A Case of Intra-Abdominal Torsion of the Omentum.—J. Hochenegg reports a highly interesting case, which is probably the only one of its kind ever published. It is that of a man, forty-one years of age, with congenital hernia, who suddenly developed symptoms of abdominal inflammation, pointing to appendicitis with sacculated exudate. However, the operation revealed a threefold torsion of the omentum, the particularly remarkable features being that the twisting of the pedicle had occurred entirely intra-abdominally, the sac being empty, and that the omentum was not adherent to any of the neighboring organs. The patient made an excellent recovery.

Münchener medicinische Wochenschrift, April 3, 1900.

Dormiol.—Peters has used dormiol for the past nine months in various conditions. It consists of one molecule of chloral, combined with one molecule of amyleuchydrate, and is an oily, colorless fluid, of a specific gravity of 1.24, a camphor odor, and a cooling taste. It has been used in organic and functional nervous diseases, and in other affections in which insomnia is a prominent symptom. It is given in ten-per-cent. watery solution or in gelatin capsules. It is agreeable to the taste, and no bad effects are noted on the heart, kidney, bladder, etc. In eighty-four per cent. of the cases a deep sleep was produced. It is especially useful in functional neuroses. The initial dose is gr. viiss., increasing to gr. xv.

Causes of Climacteric Hemorrhages.—Theilhaber says that in many instances we find carcinoma of the vaginal portion of the cervix uteri, of the mucous membrane of the cervix, or less frequently of the body of the uterus; still less frequently polypi and sarcoma of the uterus are found. Inflammatory conditions of the adnexa are rare in advanced age. "Hyperplasia uteri præclimacterica" is a source of these hemorrhages. Apoplexy of the uterine vessels, analogous to hemorrhagic infarcts, is occasionally a source of climacteric hemorrhage.

Embolism of the Mesenteric Arteries.—Ott states that, though embolism of the mesenteric arteries is rare, it is still more frequent than generally supposed. Two cases, with a typical history, course, and recovery, are reported. The necessary symptoms for a diagnosis are a source of the embolus, intestinal hemorrhage, reduction of body temperature, colicky abdominal pains, tympanitic distention, and rigidity of the abdomen, the presence of some exudate in the abdominal cavity, and the pre-existence or coexistence of other emboli.

Tannopin (Tannon) as an Intestinal Astringent.—Eugen Doernberger recommends as an intestinal astringent, especially for children, tannopin, which is a condensation product of tannin and urotropin. The dose for children is gr. viiss. three times daily, for adults gr. xv. three times a day. The dose must be regulated for the individual case. It is especially applicable to children, since it is tasteless; its greatest disadvantage is the expense. Successful cases are tabulated.

The Influence of Ichthalbin on Metabolism and the Intestinal Function in Children.—By Rolly and Saam.

A Journey in the Famine Districts of Central and East Russia.—By Lehmann.

Epileptic Equivalents.—By Ernst Schultze.

French Journals.

Action of Salicylate of Sodium upon Nutrition and in Particular upon the Secretion of Bile.—A report taken from the Société de Médecine et de Chirurgie Pratiques, the author's name not being given, contains fourteen conclusions, among which are: That under the influence of the drug a slight diminution in diuresis is noted, and an increase in the coloring matters, uric acid, and acidity of the urine. The biliary secretion is increased, as are also the phosphoric acid and fixed matters. The property of the drug in increasing the activity of the biliary function, and the known property of the bile in retarding products of fermentation in the intestine even when it contains no salicylate of sodium, together with the other properties of the drug, make its application of great interest in pathology.—*Journal de Médecine de Paris*, April 8, 1900.

A Case of Chyliform Ascites.—L. Z. Kahn records a case which came to autopsy in which the abdomen of a woman, aged sixty-six years, was distended with a milky fluid. Stomach cancer was found extending to the peritoneum. There was no solution of continuity of the lymphatic channels to account for chylous ascites. Chylous ascites, chyliform ascites, and milky ascites form together a group presenting an exterior appearance only to bind them together. They may be encountered in all affections with ascites in which they present always the same clinical characters. They have therefore no diagnostic value. There has never been a cure in any one of these forms.—*Le Bulletin Médical*, April 7, 1900.

Modern Conceptions of Neuron and Nerve Plexus.—A. Sicard discusses the ancient reticular theories, the cellular or neuron theory, and recent reticular and fibrillary theories. He concludes that the neuron theory should stand because it is founded on positive anatomical observations. No one has yet shown that the appearances are deceptive or result from faulty technique. Anatomical objections have been refuted. Physiology opposes nothing tenable against the theory. Other conclusions are also given. The article is illustrated.—*La Presse Médicale*, April 7, 1900.

Nasal Obstruction in the New-Born.—Leopold Cauveau considers the various causes for difficult breathing in infants: Superficial lesions at the nasal orifices; acute coryza; coryza in the eruptive fevers; pseudo-membranous coryzas; those produced by foreign bodies; syphilitic coryza; adenoid vegetations; retro-pharyngeal abscess; and congenital occlusions. The distinction between that due to syphilis and the other forms is of much importance.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, April 8, 1900.

Hypogastric Meatus.—X. Delore gives an account of an operation by suprapubic section and establishment of permanent fistula in a case of cancer of the prostate, with survival for eleven months in comparative comfort. The patient died of a pneumonia during the evolution of a generalization of the cancerous process. In most cases operation for cancer of the prostate can be but palliative. Hypogastric meatus meets most of the requirements.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, April 5, 1900.

Treatment of Acne.—D. Leistikow, basing his views upon the pathological conditions present, gives rules for rapid and slower cure of acne in its various clinical forms. Formulæ recommended by well-known dermatologists are given, as well as prescriptions for acne varioliformis.—*La Médecine Moderne*, April 4, 1900.

Archives of Pediatrics, April, 1900.

The Treatment of Whooping-Cough without Drugs.—N. R. Norton writes of (1) the administration of carbonic acid gas by rectum, and (2) the use of O'Dwyer's laryngeal tube. The treatment by gas was given three times daily, two or three hours after meals. In infants, the treatment lasted five minutes each time; in the "runabouts," ten minutes. Ephraim explains the effect as the result of the extra oxygen that reaches the air vesicles, there to be exchanged for the extra amount of carbonic acid gas. Of one hundred and fifty children thus treated, one hundred and forty-three were apparently decidedly benefited. As to the laryngeal tube, O'Dwyer held its use to be justifiable, provided the tube was of hard-rubber, in grave cases of whooping-cough accompanied by frequent and severe vomiting, with consequent loss of flesh and strength. By this means the spasm of the glottis is absolutely relieved.

Drug Values as Observed in the Management of Seven Hundred and Fifty-two Cases of Whooping-Cough.—Charles Gilmore Kerley reviews the effects of a number of drugs, and concludes that: (1) Every case of whooping-cough may be ameliorated either by modifying the severity or diminishing the number of paroxysms. In many cases both effects may be obtained. (2) Remedies sedative in character, with fresh air, give the best results. (3) If the remedy is to be of service, its effects will be noticed within twenty-four hours—always within forty-eight. (4) The best results are obtained when the antipyrin and bromide are commenced at the height of the paroxysmal stage and then pushed. (5) The effect of these remedies may be lost in a prolonged case, requiring a change of treatment. (6) Children may have whooping-cough and never whoop.

A Case of Congenital Goitre and Diaphragmatic Hernia.—Isaac A. Abt reports an interesting case of this kind, with illustrations. Congenital goitre is comparatively rare. It has been observed particularly in mountainous regions, where the condition is endemic. This affection occurs also in animals. Congenital diaphragmatic hernia is of comparative infrequency. In most cases, it is the result of arrest of development. Its recognition during life is extremely difficult, and consequently the condition is apt to be overlooked. The greatest danger to these children is to be expected in the first few days of life or during the act of birth.

Hypertrophic Pyloric Stenosis in Infancy.—Eric Pritchard, after reporting twenty-four cases, concludes: (1) That the hypertrophy is secondary to over-action of the sphincter, and the stenosis chiefly due to spasm; (2) that the stenosis, as measured "post mortem," is but an accurate gauge of its organic degree during life; (3) that over-action and inco-ordinated contractions of the sphincter may be due to some fault in the nervous mechanism; (4) that injudicious feeding, either quantitatively or qualitatively, may be a contributory factor of the nervous inco-ordination.

A Note upon Kernig's Sign in Infants.—Frederick A. Packard calls attention to the possible error that might arise from attaching too much importance to this sign in infants, although it is of undoubted value in the diagnosis of meningitis in the adult and in older children. He reports three cases, all of which were proved by autopsy to have had meningitis, and in all of which this sign was absent during life. These cases were aged sixteen months, sixteen months, and four months respectively.

The Medical Chronicle, April, 1900.

The Treatment of Necrosis of the Frontal Bone.—Arthur H. Burgess dresses the ulcer with hydrochloric acid of a strength sufficiently great to dissolve the lime salts contained in the exposed bone at its base, *i.e.*, ten per cent. This is applied on a double fold of lint, cut to the shape of the necrosed area, and covered with a layer of gutta-percha tissue; over this is placed lint smeared with boracic ointment, a pad of absorbent wool, and a bandage. This is left on for twenty-four hours, then removed, and the ulcer washed with boracic acid, and pepsin in the powdered form dusted lightly over the surface. The lint, impregnated with a 0.2 per cent. solution of hydrochloric acid, is applied as before. The dressing is removed next day, and replaced by the strong acid dressing, and so on alternately. By this means the bone is slowly dissolved, the necrosed parts are cast off, and a healthy granulating surface is left. The boracic-acid dressing is used, cicatrization proceeds, and the ulcer becomes covered with epithelium.

Salol and Petroleum in the Treatment of Infantile Diarrhœa.—W. E. Fothergill and John Penny made careful observations in cases of bottle-fed infants. Unsatisfactory results were obtained in eight; the remaining sixty children recovered on salol or on petroleum; twenty-eight children recovered from their diarrhœa on salol alone; thirty-one recovered rapidly and completely without any treatment beyond the administration of petroleum emulsion. One dose of salol every day combined with three or four doses of petroleum has proved very useful in many subacute and chronic cases. Bismuth may, of course, be used at the same time. Calomel and hydrarg. cum creta act better when followed by petroleum than when taken in conjunction with mixtures of a more classic nature. The observations reported teach that the various forms of infantile diarrhœa can usually be successfully treated without the use of opium in any form, and also without astringents.

A Case of Aneurismal Varix and Injury to the Median Nerve at the Elbow.—J. E. Platt describes a case of varix, due to the lodging of a piece of steel in the brachial artery, with division of the median nerve for the outer three-fourths of its extent. The brachial, radial, and ulnar arteries were tied on each side of the communication with the vein. The ends of the nerve were freshened and brought into accurate approximation by fine silk sutures. The median basilic vein was ligated. After division of a motor nerve, even if the cut ends be accurately sutured shortly after the accident, a considerable time is necessary for the functions of the muscles supplied by it to be fully restored. The time necessary is more prolonged when the nerve is injured nearer to the trunk. Under the most favorable conditions it takes from three to six months for complete recovery of muscular power after section of the median or ulnar nerve at the wrist, and in certain cases may take as much as twelve months. Sensation may return very early.

Two Cases of Tumor of the Bladder.—F. A. Southam reports these cases, which are good illustrations of the fact that for a long period a painless hæmaturia is often the only symptom given by a papilloma of the bladder. In epithelioma pain and irritability of the bladder are always early symptoms, often preceding the onset of hæmaturia. Though recurrent attacks of painless hæmaturia may be the only symptom for months, or even for years, in cases of papilloma, sooner or later cystitis is set up, being often excited by retention of blood clots in the interior of the viscus, and the straining efforts which attend the attempts to expel them; then there are superadded pain and all the other symptoms of cystitis.

Practice and Precept in Children's Diseases.—By T. C. Railton.

Bulletin of Johns Hopkins Hospital, March, 1900.

Notes on an Improved Method of Removing the Cancerous Uterus by the Vagina.—Howard A. Kelly states that glandular metastases, which play such an important part in the extension of mammary cancer, are relatively unimportant, and, as a rule, only observed in the latest stages of uterine cancer. The latter growth extends progressively through the tissues from its cervical focus, and the great aim of the operation for its extirpation is to give the diseased cervix the widest possible berth, instead of being, as before supposed, the removal of the uterus plus the extirpation of the pelvic glands. The enucleation is begun on the vaginal side, far below the limits of the invasion. The writer emphasizes the importance of catheterizing the ureters as a preliminary to the radical operation. The method of enucleation is carefully described, and after its accomplishment the anterior and posterior peritoneal surfaces are drawn down, attached to the vagina, and again sutured in the middle line. This leaves only two small openings into the pelvis, which are loosely stuffed with gauze.

A Preliminary Report on the Surgical Treatment of Complicated Fibroid Tumors of the Womb, with a Description of the Two Methods of Operating.—Howard A. Kelly describes his method of operating in the first of these cases as follows: Two long-jawed pedicle forceps were used, one on either side. One of the open jaws of the forceps was thrust through the capsule of the tumor at about the level of the round ligament from the front of the broad ligament until the point appeared on the posterior surface of the tumor behind the broad ligament. The forceps was then clamped powerfully down on the uterine and ovarian vessels, entirely controlling the circulation. The uterus was bisected and the incision was continued down into the tumor as far as the vesical peritoneum, which was freed and pushed down, when the tumor was completely bisected. The right and left halves were then enucleated. The two halves of the uterus were enucleated separately, the bed of the tumor was closed by buried sutures, and the vesical peritoneum was drawn over and attached to the posterior peritoneum, concealing the wound.

The Pathological Findings in a Case of General Cutaneous and Sensory Anæsthesia without Psychical Implication.—Henry J. Berkley, after reviewing this case, states that the fundamental pathological basis for the nervous phenomena of this case is as follows: (1) A hyaline-fibrous degeneration of the arterial system existed, not confined to the central nervous regions, but equally evident in the roots of the spinal nerves and in the skin tissues. This varied in degree from slight thickening of the muscular layer to complete closure of the lumen from hypertrophy of the middle coat of the vessel walls. The maximum alteration was in the vessels of the lower dorsal cord, the meninges of the bulb and cord, and in certain of the root bundles of the cerebro-spinal nerves. (2) As a consequence of the vascular lesions, there were degenerations of an atrophic order in the nerve cells of the gray horns of the cord, particularly in Clarke's column and the medulla oblongata.

Observations upon the Neural Anatomy of the Inguinal Region Relative to the Performance of Herniotomy under Local Anæsthesia.—Harvey Cushing, after carefully reviewing this subject, sums up the advantages of the local anæsthetic. There is an avoidance of unpleasant or dangerous post-etherization sequelæ. There is no vomiting or retching. Urinary disturbances are much less apt to occur, and catheterization is rarely necessary. The diet may practically be continued as before the operation. There is no backache. The dressings may be applied originally to suit the comfort of the patient, and there is no subsequent disarrangement of them. Above all an advantage is gained in being able to operate with comparative safety in patients who would incur immediate risk in submitting to general anæsthesia. The disadvantages seem trivial: the operation is longer, and there is some distraction to the surgeon.

Congenital Malformations of the Heart as Illustrated by the Specimens in the Pathological Museum of the Johns Hopkins Hospital.—By W. G. MacCallum.

Pediatrics, April 15, 1900.

Some Reasons Why Tuberculosis Spreads More Rapidly among Cattle than in the Human Race.—Walter W. Gardiner shows by diagram of stable, etc., how an infected cow becomes a source of infection to other cows through the water pot and fodder trough. One tuberculous cow in a modern barn may during a winter infect a whole herd. The prevalent lines of breeding followed generation after generation detracts from the vitality and power of resisting disease. The disease develops most rapidly at a temperature of 101°–103° F. The normal temperature of the cow is 101°, and when in a warm stable and grain-fed it may reach 102°, or the temperature at which tubercle bacilli will thrive best. Generations of in-breeding are factors which favors the cow's greater susceptibility.

Nephritis in Childhood.—Moncorvo goes over the literature and dwells especially upon the nephritis which occurs in the course of malaria. Scarlatinal nephritis is rarely found in the pathological reports of Rio de Janeiro, because scarlatina occurs so infrequently there. Malarial nephritis has hitherto attracted but little attention. The author called attention to it in 1895. In thirty-five recent cases twenty-six coexisted with malaria. Examples are related showing that in the young malaria plays the same part as does scarlatina in cold and temperate climes. They are usually benign, terminating favorably. The œdema is often in the nature of true anasarca.

The Care of Premature and Feeble Infants.—By S. W. Ransom.

Annals of Gynecology and Pediatry, March, 1900.

The Correlation of Sexual Function with Insanity and Crime.—H. Macnaughton-Jones concludes that the correlation of insanity and disordered sexual functions, arising out of affections of the generative organs, is a factor to be taken into serious consideration in the treatment of women mentally afflicted. When there is ground for the suspicion that some abnormal condition of the genital organs exists which is causing the mental condition, examination, under an anæsthetic if necessary, should be made. The special dangers of the climacteric period and the symptoms indicative of threatening mania must be noted. Women who have been previously insane are predisposed to a relapse by the development of disease in their sexual organs, especially to temporary recurrence of insanity after operation on these organs.

Some Remarks on the Operative Treatment of Uterine Fibroids.—W. J. Gow writes that in his series of forty-seven cases there has been one death. He believes that abdominal hysterectomy, properly performed, is not so dangerous an operation as it is generally thought to be, and, further, that the subperitoneal treatment of the stump gives as good or better results than any other plan. The writer has not in one of these cases done an oöphorectomy. Drainage was employed only on one occasion. The lessened mortality of abdominal hysterectomy enables the surgeon to save patients not merely from death but from invalidism.

Some Pathological and Clinical Phases of Gall Stones.—A. H. Cordier states that cholelithiasis is of frequent occurrence, and usually gives rise to manifest symptoms, either severe or obscure. Cholesterin, as a gall-stone-producing agent, must be present in an abnormal quantity, and is in great measure a product of the destruction of the epithelium of the biliary ducts and gall bladder. Bilirubin calcium forms the nucleus of the majority of stones. Jaundice, ptomain poisoning, and suppuration are late symptoms of cholelithiasis. Dyspeptic symptoms and loss of weight are some of the remote results.

A Case of Bilharzia Hæmatobia.—Edwin Walker describes the case of a woman in whose bladder this parasite was found. The urine was pale, specific gravity 1.001–1.006, reaction neutral, and containing but little urea. In this fluid were the ova and embryos of the parasite. The treatment consisted of santonin gr. v. three times a day, and bicarbonate of potassium in large doses. The ova disappeared in a few weeks, but since some blood has been passed at times. The parasites have been found in most parts of Africa.

A Case of Porro's Operation.—Milo B. Ward cites a case whose special points of interest are: The absence of any history of rupture of the amniotic sac; the oblique and fixed position of the uterus, preventing the possibility of uterine contraction; no symptoms of labor were present, but constant backache; the gangrenous condition of the endometrium with entire destruction of the placenta, yet no marked disturbance of the patient's health; the patient's excellent recovery.

Monatsschrift für Geburtsh. und Gynäk., April, 1900.

Contribution to the Knowledge of Placental Tumors.—G. W. van der Feltz reports two cases, on the basis of which, in connection with a most careful study of the literature, he comes to the conclusion that the term "neoplasm" generally applied to these placental anomalies is a misnomer. He claims that these so-called placental tumors do not answer the requirements of a neoplasm, and seems to furnish ample proof for his assertion. It is his opinion that the anomalies in question are but transformed villi with a more or less pronounced increase of connective tissue; and that hence there is no justification for the terms myxoma, fibroma, etc.

Contribution to the Knowledge of the Serous Infiltration of the Para-Uterine Connective Tissue and its Extension into the Region of the Subserous Cavity in the Living.—E. Ehrendorfer describes a very interesting case of extensive subperitoneal infiltration which he believes to be the only one reported in the literature. He states that while he, and no doubt others likewise, have frequently observed a pretty thorough serous infiltration of the parametric protoplasms, when extirpating fibromyomata, he has never seen so intense and extensive a subperitoneal serous effusion in abdominal tumors.

Primary Tumor Formations of the Nipple and Mammary Areola.—A. O. Lindfors publishes most valuable statistics, comprising thirty-seven cases of primary tumors of the mammilla and areola, collected in the literature. Ten of these refer to the areola, twenty-seven to the papilla mammæ; seven occurred in men, thirty in women. He states that only the myomata and pedunculated tumors can be classed as absolutely benign; the other forms are already malignant at the beginning or become so sooner or later. As regards recurrence after the operation, he has been unable to obtain sufficient data.

Vaginal Operations in Cases of Extra-Uterine Pregnancy.—Max Madlener reports two cases. The first one, in which posterior elytrotomy was done, shows that a child carried to full term may be removed from its fœtal envelope through the vagina. The second case was one of tubal pregnancy in which an anterior colpotomy was performed. Although both operations were successful, the author declares that he will never again undertake colpotomy in cases in which extensive adhesions are to be expected. He believes that the field for this operation is a very limited one.

Concerning the New Building to be Erected for the Imperial Clinical Institute for Obstetrics and Gynæcology, at St. Petersburg.—By v. Ott.

The Orthopædic Results of the Alexander-Adams Operation.—By B. Kroenig and J. Feuchtwanger.

Reviews and Notices.

GENERAL AND LOCAL ANÆSTHESIA. By AIMÉ PAUL HEINECK. Pp. 124. Chicago: G. P. Engelhard & Co. 1900.

THIS monograph should be read by all who are engaged in administering anæsthetics. It treats the subject in a most thorough and concise manner, enumerating the dangers and the causes thereof, with the treatment and prophylaxis employed for each. Most of the space is devoted to chloroform, ether, and cocaine, with a brief yet sufficient description of the infiltration method of anæsthesia.

THE MODERN TREATMENT OF WOUNDS. By JOHN E. SUMMERS, JR. 149 pages. Omaha: Medical Publishing Co. 1899.

TO one who would inform himself briefly, yet accurately and well, upon the latest principles of surgical technique, and the therapeutic procedures which are practised in wounds of the special regions, a book like the one before us will always be acceptable. The author has presented the subject-matter very well. Exception might be taken to his general use in infected wounds of pure carbolic acid followed by its neutralizant alcohol; for whereas this procedure has certainly been followed by excellent results in some cases, yet we must never forget that it destroys the tissue cells as well as the bacteria, and so diminishes the resistant power of the affected part. The book is well printed and contains a few good illustrations.

IMPERATIVE SURGERY. By HOWARD LILIENTHAL, M.D. 8vo, 412 pages. Illustrated. New York: The Macmillan Co. 1900.

THE author has intended this book for the use of the general practitioner and recent graduates in medicine, and deals only with the diagnosis and treatment of conditions which demand immediate operative measures. The opening chapters, which are given up to antiseptic and aseptic surgery in general, including a description of how to prepare for an operation in a dwelling-house, are particularly good, and will be of especial interest to all physicians who have not had the benefits of a general surgical training. In the chapters devoted to regional surgery, the author, by mentioning but one good type of operation for each pathological condition, has removed from the shoulders of those who do not devote themselves to surgery, and who are therefore hardly capable of selecting the best method to be practised, the onerous duty of deciding which operative procedure to employ. It may be said in general that the symptoms and diagnosis of the special surgical diseases are concisely pictured, the indications calling for "imperative surgery" clearly outlined, and the methods of operating briefly and yet minutely described. A complete index is appended. The book is richly and excellently illustrated, from entirely original photographs and drawings. The author has certainly supplied to those who practise surgery only when absolutely necessary a valuable work, and both he and the publishers are to be heartily congratulated on the manner in which the book has been prepared.

MANUEL PRATIQUE D'HYGIÈNE À L'USAGE DES MÉDECINS ET DES ÉTUDIANTS. Par le DR. GUIRAUD, Professeur d'hygiène à la faculté de médecine de l'Université de Toulouse. Deuxième édition, revue et augmenté. Paris: G. Steinheil. 1899.

THIS is a very excellent handbook for the use of practitioners and students of medicine and for those interested in the problems of hygiene. Its scope is broader than that usually embraced by a work of the kind, for it not only has for its object the conservation of health, but also the improvement of the general conditions of the individual and of the community. The work contains the applications of the latest discoveries and experiments in chemistry and physiology to the body of man, and in maintaining it in sanitary relation to his environment. The effects of the soil, the atmosphere, and the climate are discussed in connection with disease and healthful and unhealthful occupations. Clothing, ventilation, dwellings, the care of the body, and exercise are treated broadly and thoroughly from the several standpoints of age, race, custom, locality, profession, and occupation. The conditions of human life in its modern transformation are sensibly dealt with; the problems of overcrowded cities, the complex social relations, the development of new industries, and the struggle for existence are all recognized as factors in the health of the race. Perhaps the most valuable and up-to-date chapters of the book treat of the affections which until recent times have so often been termed "the scourge of the Lord," the infectious diseases that sweep over whole countries. The methods of preventing these murderous plagues are clearly and concisely shown, by pointing out the sources of infection, the practical means of disinfection, and the laws of sanitation that must be observed to check the various diseases. The work comes to us as a fat, compact, well-printed, badly bound volume of about eight hundred pages, in the cheap paper covers that our foreign works don to make the sea voyage; but it is worthy of a place on the shelves of every one who would attempt to solve the many questions that are constantly confronting the student of municipal sanitation.

L'APPENDICITE, FORMES ET TRAITEMENT. Par A. BROCA, Professeur Agrégé à la Faculté de Médecine de Paris, etc. Avec 8 Figures dans le Texte. Les Actualités Médicales. Paris: Librairie J. B. Baillière et Fils. 1900.

THIS is an interesting little monograph upon the subject of appendicitis, in which the author's conclusions are drawn mostly from his own experience, so that some of them are a little different from what is supposed to be the consensus on the subject at present. This is, however, not necessarily a drawback in a work on any subject. The various forms of appendicitis are clearly described, and a discussion of the modes of treatment leads the author to his conclusion that timely surgery alone is proper, though he states that this does not mean immediate operation in every case. The description of operations in the quiescent period is certainly incomplete without reference to the work of American surgeons in this field.

SYSTEM OF DISEASES OF THE EYE. By American, British, Dutch, French, German, and Spanish authors. Edited by WILLIAM F. NORRIS, A.M., M.D., and CHARLES A. OLIVER, A.M., M.D., of Philadelphia, Pa., U.S.A. Volume IV.: Motor Apparatus, Cornea, Lens, Refraction, Medical Ophthalmology. With 51 full-page plates and 211 text illustrations. Philadelphia and London: J. B. Lippincott Co. 1900.

THIS volume, like the others of this system, is, on the whole, most excellent. It contains sixteen articles by authors of different nationalities. The translations are exceptionally good, apparently fully presenting the ideas that were expressed in the original manuscripts. The first article is by Edmund Landolt, M.D., on "The Anomalies of the Motor Apparatus of the Eyes." It occupies one hundred and sixty-seven pages, and is very creditable. The second article, which treats of "Diseases of the Cornea," is one of the weak parts of the volume. The chapter on diseases of the crystalline lens, that follows, is comprehensive and up to date in every particular. A discussion of ametropia occupies the next chapter: it consists of an exposition of the views of the author on the subject, evidencing careful observation and study. Much that is speculative, argumentative, and advisory is found here. The article on "Ocular Lesions dependent upon Diseases of the Circulatory System" is exhaustive and of much value. "Eye-Diseases and Eye Symptoms in their Relation to Organic Diseases of the Brain and Spinal Cord" forms the title of a very carefully written article, which could be produced only after extensive research and profound consideration of the subject. The articles entitled "Ocular Lesions dependent upon Disorders of the Secretory and Excretory Organs," "Ocular Lesions in Variola," etc., and the "Ocular Lesions of Influenza, Dysentery," etc., are all excellent, treating of the subjects in a clear, succinct manner. The article on "The Ocular Manifestations of Hysteria" is somewhat unsatisfactory. "Eye Affections due to Graves' Disease and Herpes Zoster," a contribution by Jonathan Hutchinson, Jr., is brief and as complete as the space permits. "Motor Changes in the Ocular Apparatus Associated with Functional Neuroses" is the title of the next article; it consists of a narration of cases observed by the author, and an expression of individual views. The name of the author, George E. de Schweinitz, M.D., is a sufficient guarantee of the excellence of the article on "Toxic Amblyopias" which follows; exhaustive, clear, concise, it is one of the gems of the collection. Following this article are those entitled "The Entozoa of the Human Eye," "Simulated Blindness," and "The Ocular Signs of Death." All are of merit. The contributors have won enviable reputations in the fields of research which they here represent; however, some of the articles are not of the exhaustive character that one would expect to see in a system of diseases of the eye which purports to cover the whole subject with the greatest completeness. Evidence of crowding, which cannot be eliminated in a work the extent of which is fixed at the outset, is apparent here.

The Lute and Lays. By Charles Stuart Welles, M.D. New York: The Macmillan Company. London: George Bell & Sons. 1899.

A collection of about sixty short but pleasing poems, or "songs" as the author calls them, composed in and some about America. The presswork is characteristic of the house.

The Retrospect of Medicine; a half-yearly journal. Edited by James Braithwaite and E. F. Trevelyan. Vol. 120, January, 1900. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited.

This semi-annual review of medicine and surgery continues to present in an attractive way much of the progress made in different lands, but chiefly abstracted from English and American sources.

The International Medical Annual Synoptical Index to Remedies and Diseases, for the twelve years 1887 to 1899. New York: E. B. Treat & Co. 1900.

The aim has been to present an index of facts likely to be wanted for reference in everyday practice. Even to those who do not possess the twelve volumes here systematically indexed with reference to drugs and diseases, it will be of use to those looking up any given subject, covering as it does a very wide range of literature and giving the important points in regard to new remedies. There is a supplementary index for cross references.

A Practical Treatise on the Disorder of the Sexual Organs of Men. By Bukk G. Carleton, M.D., Genito-Urinary Surgeon and Specialist to the Metropolitan Hospital and Polyclinic; Consulting Genito-Urinary Surgeon to the Hahnemann Hospital, etc., New York. Revised and enlarged edition. New York: Boericke & Runyon Co. 1900.

The work as it now stands is twice the size of the original edition. There have been added anomalies, injuries, and non-venereal diseases of the male genital organs. The latest special methods of treatment have received recognition. It is justly stated that surgical treatment is often required before the selected remedy will remove the morbific phenomena, and modes of procedure are brought up to date. The author is to be congratulated upon the early exhaustion of his first edition.

A Practical Treatise on Diseases of the Skin, for the use of students and practitioners. By James Nevins Hyde, A.M., M.D., Professor of Skin, Genito-Urinary, and Venereal Diseases, Rush Medical College, and Frank Hugh Montgomery, M.D., Assistant Professor of Skin, Genito-Urinary, and Venereal Diseases, Rush Medical College, Chicago. Fifth and revised edition. Philadelphia and New York: Lea Brothers & Co.

The outside cover, the two names upon the title-page, the increased size, and especially the new monochrome and colored plates would cause one almost to think a new book lay before him. Opening to the frontispiece, however, one feels at once at home with his old friend Nævus Lipomatodes of the hairy back and pendulous buttock. Other friends are recognized as the pages fall away from the thumb. It is perhaps natural that the authors should feel a reluctance to part with time-honored pictures, but the leprous gentleman on page 701 and the specific lady on page 655 have reached an age when they should be put on the retired list. The new illustrations are of a much higher order of excellence than many of the old, and add decidedly to the interest of this new edition. In the matter of pathology there is an appreciable improvement in many chapters, reflecting most of the recent investigations, while scarcely a new discovery in dermatology up to the date of issue has been overlooked. Among these may be mentioned especially blastomycetic dermatitis and porokeratosis. Many chapters have been wholly rewritten or revised and brought well up to date. There are twelve new full plates and two engravings. The work has proven justly popular.

A Manual of Surgery. By Charles Stonham, F.R.C.S. Eng., Senior Surgeon to Westminster Hospital, Lecturer on Surgery and Clinical Surgery, and Teacher of Operative Surgery, Westminster Hospital. 3 vols. 12mo. New York: The Macmillan Co. London: Macmillan & Co. 1900.

The volumes are amplified much beyond the scope of ordinary manuals, but are not complete enough for what is generally recognized as fulfilling the conditions of an elaborate treatise. They may be said to occupy, however, a very desirable middle ground especially adapted to the requirements of the student and general practitioner. Under the different divisions of general surgery, injuries, and regional surgery a vast and varied field is covered, comprising all the essential facts which are of practical value to the busy worker in different lines who has neither time nor opportunity for consulting larger works. The style is necessarily concise, which is itself a great recommendation, and the illustrations are numerous and carefully selected. All the topics are treated from the teacher's standpoint and are thoroughly up to date.

A Manual of the Practice of Medicine, prepared especially for Students. By A. A. Stevens, A.M., M.D., Professor of Pathology in the Woman's Medical College of Pennsylvania; Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania; Physician to St. Agnes' Hospital and to the Out-Patient Department of the Episcopal Hospital, etc. Fifth edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders. 1898.

The fact that this work has gone through five editions speaks for its popularity, and for students it certainly is most useful, giving concrete descriptions of nearly all diseases, etiology, pathology, symptomatology, diagnosis, prognosis, and treatment This, the fifth-edition, has been thoroughly revised and many of the articles have been rewritten. Among the new subjects are: Acute Cholecystitis, Tuberculosis of the Kidney, Gastroptosis, Enteroptosis, and Chronic Cerebral Leptomeningitis. The work is published in a handy form, with a flexible leather cover, and makes an excellent vade mecum.

The Vagina and Perineum, and how to Mend Them. By Byron Robinson, M.D. 134 pages. Chicago: The Clinic Publishing Co.

The *raison d'être* of a medical book should either be the presentation of a new subject, or of an old one in an original manner, and in either case the facts should be stated by the author accurately and tersely. The book before us lacks most of these essentials, and the really important part, viz., the anatomy and function of the pelvic fasciæ, is obscured by too frequent repetitions. Altogether had the author devoted one-eighth the space he has to this volume, and been more accurate in his descriptions, the object he had in view, which was to point out the importance of the pelvic fasciæ in perineal lacerations and in their repair, would have been better accomplished. The book contains numerous illustrations of the muscular and fascial structures of the pelvis, and of the operative procedures which have been designed for their repair after laceration.

International Text-Book of Surgery. By American and British Authors. Edited by J. Collins Warren, M.D., LL.D., Boston, Mass., and A. Pearce Gould, M.S.F.R.C.S., London, Eng.: Vol. II., Regional Surgery. 8vo, 1044 pages. Philadelphia: W. B. Saunders. 1900.

This is a work without introduction or other pretension of excellence, and which comes to us on its own intrinsic merits. Of the latter it has very many. The arrangement of subjects is excellent, and their treatment by the different authors is equally so. The work is divided into thirty-three chapters, which comprise all the conceivable subjects liable to come under the notice of surgeon or general practitioner. What is especially to be commended is the painstaking endeavor of each writer to make his subject clear and to the point. To this end particularly is the technique of operations lucidly described in all necessary detail. This is the case above all with the chapters on abdominal surgery, wherein are treated the surgical diseases of intestines—including, of course, appendicitis and the operations upon the bile ducts. These as well as other portions of the work are suitably illustrated, so that the merest tyro can gain a clear idea of the indications in a given set of cases. And withal the work is up to date in a very remarkable degree, many of the latest operations in the different regional parts of the body being given in full detail. There is not a chapter in the work from which the reader may not learn something new—at least such was the case with the reviewer, which fact may excuse him from the charge of any partiality when he unqualifiedly recommends the work to all in need of a first-class guide.

OPERATIONS-VADEMECUM FÜR DEN PRAKTISCHEN ARZT. Von DR. EDMUND LESER, Professor an der Universität Halle. Mit 144 Abbildungen. Berlin: Verlag von S. Karger. 1900.

As its title indicates, this is a handbook of surgery for the practitioner who is not specially a surgeon. There is no attempt made to cover the whole field of operative surgery, but only those operations are described the performance of which may be required when there is no specialist at hand. There are many good illustrations, and the different procedures are tersely described. The author recommends ether as the anæsthetic of choice, and does not mention any of the modern operations for the removal of the diseased but quiescent appendix.

PROGRESSIVE MEDICINE: A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D. Volume IV., December, 1899. Philadelphia and New York: Lea Brothers & Co. 1899.

THIS last volume of the year takes in diseases of the digestive tract, genito-urinary diseases of the male, syphilis, fractures, surgery of the extremities, orthopedics, diseases of the kidneys, physiology, anatomy, hygiene, and practical therapeutics. The contributors or sub-editors are H. B. Baker, W. T. Belfield, J. C. Bloodgood, J. R. Bradford, A. P. Brubaker, F. H. Gerrish, C. G. Stockton, and E. Q. Thornton. The work of the various editors has resulted in covering pretty well the field of more recent advances in the departments here presented. Non-scientific writers are not wholly ignored, and we find a description of Delhi boil taken from Kipling's "The Day's Work." The press-work has been done in an excellent manner.

OPERATIVE SURGERY. By JOSEPH D. BRYANT, M.D., Professor of the Principles and Practice of Surgery, etc., University and Bellevue Hospital Medical College; Visiting Surgeon to Bellevue and St. Vincent's Hospitals, etc. Volume I.: General Principles, Anæsthetics, Antiseptics, Control of Hemorrhage, Treatment of Operation Wounds, Ligature of Arteries; Operations upon Veins, Capillaries, Nervous System, Tendons, Ligaments, Fasciæ, Muscles, Bursæ, and Bones; Amputations; Deformities; Plastic Surgery. Illustrated. New York: D. Appleton & Co. 1899.

THE third edition of this well-known book is practically a new work, for it is rewritten, remodelled, and divided into two volumes, of which the present is the first. There are interesting and lucid preliminary chapters on the preparation of room and patient, on the choice of the anæsthetic, and on the instruments and apparatus in general use in the operating-room. The pre-eminence of ether as the safest anæsthetic is upheld by the author's statistics. The chapter devoted to the ligature of arteries contains many excellent plates illustrating the anatomy of the vessels, and, in addition to a discussion of the operations themselves, there are many useful historical references. There are clear descriptions of the operations for the relief of various forms of neuralgia, and again many good illustrations. The operation which in this book and elsewhere is called the Hartley-Krause operation should be called simply the Hartley operation, if priority counts for anything. The various operations upon the bones receive a large share of attention, and the surgery of the cranial bones is given special consideration both in the text and in the illustrations. The photographic plates, here and elsewhere, of the instruments used at various operations form a useful addition to the more customary illustrations. The subject of amputations is treated in a satisfactory manner, and the descriptions and illustrations are of great didactic value. The last chapter, on plastic surgery, contains among other things a description of the forms of support which have been used in restoring the saddle-shaped deformity of the nose, with the very just comment that one can never be certain that such supports will remain in place more than a limited time without causing trouble. The book is much improved over its former editions, and when complete will be one of the best on the subject. The bookmaker's work has been very well done.

Clinical Department.

THORACIC ANEURISM: TWO CASES INVOLVING THE DESCENDING ARCH OF THE AORTA; WITH AN AUTOPSY.[1]

By STEPHEN SMITH BURT, A.M., M.D.,

NEW YORK.

DURING my present service in New York Post-Graduate Hospital, and within the same month, there have been two cases of thoracic aneurism which seem sufficiently important and interesting to warrant my placing them upon record, and bringing them to the attention of the Hospital Graduates' Club. It is well known that the diagnosis of a thoracic aneurism may be a simple matter, a difficult matter, or an impossibility, according to the existing circumstances. From the smallness of its size and the position which it occupies, the rupture of a minute sacculated aneurism may be its first manifestation. And unless a fairly large dilatation of this nature impinges somewhere upon the surface of the chest, its less evident pressure symptoms are in danger of remaining unrecognized. Moreover, even when an aneurismal tumor is within reach, the amount of laminated fibrin deposited in its cavity may so modify the typical physical signs of aneurism as to render a differential diagnosis a somewhat difficult problem. On the other hand, wherever upon the surface of the thorax there is a pulsating tumor which is not the heart, but which is beating with as much force as, or with greater force than, that organ, and withal of the same rhythm, whether or not there is a bruit, in all probability it is a thoracic aneurism. Meanwhile, in the more obscure cases, the extreme rarity of a non-aneurismal thoracic tumor is a fact which I am convinced it is the part of wisdom always to take into consideration. Aneurisms of the thoracic aorta are much more common than those of the abdominal aorta. Aneurisms of the descending portion of the arch of the aorta are rare as compared with the ascending or even the transverse. Those familiar with the investigations of Sibson know that out of 880 aortic aneurisms, he found 703 were of the thoracic aorta, and the remainder of the abdominal and its branches. Of these but 72 were of the descending portion of the arch. There were 120 of the transverse, and 193 belonging to the ascending aorta; ascending and transverse aorta conjointly, 112; transverse and descending portion of the arch, 20; descending thoracic aorta below the arch, 71; whole arch, 28; sinuses of Valsalva, 87. The two cases brought to your notice this evening were situated in the descending portion of the arch of the aorta, but they differed materially in their physical signs and their symptoms. Rupture is the most common termination of an aneurism. Pressure upon the trachea by an aneurism of the descending arch is quite exceptional. In one of the following cases death was due to exactly this condition; in the other it was due to a rupture with hemorrhage, probably into the left bronchus.

---

[1] Read at the meeting of the Hospital Graduates' Club, January 25, 1900.

Case I.—Thomas D——, age thirty-four years, single, occupation clerk, came under my observation December 1, 1899. Family history: His father was living and in good health; his mother died of some heart trouble; four brothers and one sister were all dead; the causes of death were unknown. Previous history: He had rheumatism when sixteen years of age, and the grippe ten years ago; he had pain in the chest one year ago. Present history: About ten weeks ago he was taken with pains in his chest under his left shoulder blade, which were most severe when breathing; he has had poor appetite for the past several weeks; he sleeps poorly; he complains of pain also in the left shoulder, which extends down the left arm.

Physical examination gave the following: The apex beat of the heart was below and to left of the normal position. The impulse was strong. Respiratory movements of the left side were restricted. Pulsation was synchronous with the heart, and of nearly equal force. at the upper left side of the chest above the third rib in front. On palpation there was absence of vocal fremitus over the left side of the chest in front and behind. There was no thrill over the area of pulsation, and no "tracheal tugging." There was no increase in the semi-circumference of the left side. On percussion, flatness was found over the lower two-thirds of the left side of the chest; there was dulness at the upper part behind. There was a triangular area of exaggerated resonance with base in the upper left axillary region, and apex extending forward between the flatness below and the area of pulsation above. Dulness, with decided resistance, was found from near the right edge of the sternum across the anterior surface of the chest to the left above the level of the third rib. Auscultation showed absence of vesicular respiration in the left side of the chest. There was a loud systolic murmur, rough in quality, with the point of greatest intensity at the second right intercostal space, extending across to the left through the area of pulsation. There was accentuation of the aortic second sound, not, however, transmitted far from its source. My diagnosis was obstruction at the aortic valve, aneurism of the descending arch of the aorta, with probable occlusion of the left bronchus, complicated by pleurisy.

There were no evidences of pressure upon the trachea, œsophagus, left recurrent laryngeal nerve, sympathetic nerve, left common carotid, left subclavian artery, or left innominate vein. Chemical and microscopical examination of the urine was negative. The sputa were examined for tubercle bacilli; none was present. Temperature was normal from the day of entrance, August 30th, to within three days of death. The pulse varied from 80 to 100; respiration, from 20 to 30 per minute. There was no record of hæmoptysis. There was neither tuberculous nor cancerous cachexia. His general condition was good. His complaint was chiefly a pain in the left chest and likewise down the left arm. The area of dulness, in which were the pulsation and systolic murmur, was distinct from the region of flatness lower down, there being an interval of hyper-resonance between.

The treatment was rest and iodide of potassium gr. x., increased gradually to gr. xx. three times a day. The patient died December 20, 1899, of a sudden and very profuse hemorrhage, probably from rupture of the aneurismal sac into the left bronchus. Permission for an autopsy was refused.

Case II.—Edward T——, age thirty-seven years, colored, married, occupation porter, was admitted to hospital December 6, 1899. His family history was good. At the age of twelve years he had had frequent attacks of malaria. At eighteen he had had rheumatic pains in the knees and hips. Twelve years ago he had had pneumonia. He has never had syphilis. There was no history of alcoholism. One year ago he had a sharp pain in the left side lasting one week. Since then he has had repeated attacks of pain in the chest, shoulders, and back, and has been unable to work. At night he has a feeling of oppression in the chest, and for the past week a choking sensation in the throat.

Analysis of the urine gave the following: Reaction acid; specific gravity 1.030; color dark amber; transparency clear; chemical reaction, no sugar, small ring of albumin; on microscopical examination, no casts, pus cells very numerous, epithelium, a few squamous and round bladder cells.

The temperature was normal; pulse, 88; respiration, 24, on admission to the hospital. There was no œdema of the extremities. The voice was hoarse; no aphonia. There was cough, hoarse but not metallic in quality. The larynx was reported normal upon examination. There was no complaint of dysphagia.

A physical examination showed: The apex beat of the heart was in normal position. There was no visible pulsation elsewhere in the chest. There was no localized bulging; the superficial veins of the chest and both arms were distended. There were a spongy elastic swelling at the base of the neck and angular curvature of the spine in the upper dorsal region, with especial prominence of the spinous process of the third dorsal vertebra. No inequality of the pupils and no unilateral sweating of the face were present. Palpation showed decided pain upon pressure over the second, third, and fourth dorsal vertebræ. The apex beat was normal in force and position; pulsation was equal in strength and rhythm in the radial arteries; there were no palpable pulsation or shock in the chest outside the precordial region, no thrill, and no tugging at the trachea. On percussion, dulness was found with marked resistance, extending from one inch to the right of the sternum, across and for three inches to the left of that bone, and from the level of insertion of the third ribs in this area upward. Abnormal dulness from the third dorsal spine upon both sides behind, and marked vesiculo-tympanitic resonance from the third dorsal spine on both sides downward, were noted. Auscultation showed sonorous breathing over the entire chest and trachea, with point of greatest intensity at the lower end of the trachea and the left bronchus; vesicular respiration was either diminished in intensity or masked by the sonorous breathing; no cardiac murmurs, no thrill, no murmur over the area of dulness, nor intensification of either heart sound; there was neither systolic nor diastolic shock over the tumor or the trachea. Upon a subsequent examination slight pulsation was detected on palpation and on auscultation over the area of dulness on the left side in front, which entirely disappeared the day following.

My diagnosis was aneurism of the descending portion of the arch of the aorta, pressing upon the vertebræ behind and the lower end of the trachea and the left bronchus in front. The location of the tumor was determined by the evidences of pressure upon the vertebræ behind and the trachea and bronchus in front, and by the absence of any signs of pressure on the left recurrent laryngeal nerve, the sympathetic nerve, or of involvement of the left subclavian artery. The nature of the tumor was a question not so easily answered, owing to the absence of many distinctive evidences. Nevertheless, the vigorous frame and well-nourished condition; the peculiar shifting character of the pain except in the back; the paroxysmal expiratory dyspnœa; the fact that non-aneurismal tumors are more apt to be located in the anterior mediastinum, and that pain is more common with aneurism than with growths in the mediastinum, while the reverse holds in regard to fever and emaciation; the entire lack of evidence of cancer elsewhere; the absence of a characteristic expectoration; the absence of glandular enlargement; the age, sex, and occupation of the patient; the history of the case together with the observation of the course of the disease; the results of medication (the pain on pressure entirely disappearing from the vertebræ under the iodide of potassium); and repeated physical explorations—led me irresistibly to the conclusion of aneurism.

Treatment consisted chiefly of rest in bed, and iodide of potassium gr. xv. three times a day, with now and then, as required, morphine hypodermically.

The daily notes show that the temperature remained about normal; the pulse varied between 80 and 100, the respirations between 20 and 30 per minute. There was never a complaint of difficulty in swallowing; however, the appetite was poor, and he ate little solid food. His bowels were constipated. There was no record at any time of hemorrhage. There never was any paraplegia. He had dyspnœa with a hoarse cough which was not metallic in quality, and a slight mucous expectoration. He was less uncomfortable when lying on the back, yet there was at all times great restlessness. He complained of a feeling of fulness and oppression in the chest. He had frequent paroxysms of pain and dyspnœa, but above all toward the end a distressing dyspnœa, and finally asphyxia, which terminated in death on December 29, 1899, twenty-three days from his entrance to the hospital.

The autopsy was performed by Dr. H. A. Gribbon, a member of the house staff, in the presence of Dr. J. F. Siler, also of the house staff, and myself.

Autopsy on the body of Edward T—— (colored) January 3, 1900: General condition, well nourished. There was marked kyphosis in the upper dorsal region. The lungs, liver, spleen, and kidneys were moderately congested. The heart and stomach were normal. The brain was not examined. There was a large sacculated aneurism in the descending portion of the arch of the aorta, beginning about three-quarters of an inch beyond the origin of the left subclavian artery, and situated behind the trachea and filling the upper quarter of the left thoracic cavity, together with the posterior mediastinum, and extending about three inches into the upper part of the right thoracic cavity. The tumor pressed forward against the lower part of the trachea and the left bronchus, but was not adherent. It likewise compressed the vena cava superior and the venæ innominatæ. The walls of the aneurism were adherent on the posterior aspect to the spinal column, and on the right side somewhat anteriorly to the œsophagus. The œsophagus, with canal still patent, seemed to have been carried forward and outward on the right side of the tumor, to which it was closely adherent for about four inches. The aneurism was filled with a dense laminated fibrous clot, leaving free the channel of the aorta. The aneurismal tumor was of an irregular ovoid shape, with a long diameter of from six to eight inches. The bodies of the second, third, and fourth vertebræ were extensively eroded. The erosion of the third opened into the spinal canal. The inter-articular discs were not affected by the erosion to any degree. The borders of the second, third, and fourth ribs were roughened near the spine, and slightly eroded.

MUMPS VERSUS RHEUMATISM.

By E. W. HEDGES, M.D.,
PLAINFIELD, N. J.

One year ago there came to my office a young man suffering from gonorrhœa. This innocent infection proved most obstinate and resisted every mode of treatment. Two months later, in April, 1899, he developed a well-marked attack of rheumatism in his right foot. The ankle joint was not involved, but the top and sides of the foot were swollen and very painful. This, like the urethritis, was not amenable to treatment, and for three months the two diseases vied with one another in their power to annoy.

Some time in July the pain and swelling left the right foot and took up their home in the left foot, which in turn became tender, painful, and swollen. This continued until December 20th. Not a single day was the patient without pain and swelling. He could not walk a block without suffering, and was frequently kept awake nights by pain in his foot, meantime running the gamut of all the anti-rheumatic remedies without avail.

About the middle of November the clap stopped. The last remedy used was an injection of 1 : 4,000 bichloride solution, but whether that had anything to do with the cessation of the discharge I do not know. On December 20th he retired with the usual pain and swelling in his foot. He awoke with both parotids big and painful, but with his foot absolutely well. The mumps ran the usual uneventful course of about a week, but from its first appearance to the present time (two months) he has had no vestige of rheumatism anywhere in his body. The mumps appeared at a time when the disease was epidemic in the city, and hundreds of young and old were affected by it.

The interesting questions come up, Was the mumps merely metastatic from the rheumatism, or was it regular epidemic parotitis, and if so, is there some antagonism between the toxin of the diplobacillus of mumps and the rheumatic poison, whatever that may be? Mumps certainly cannot confer a lasting immunity to rheumatism, for we can all recall cases of the latter disease in patients who have had mumps earlier in life; but may it not have some temporary antidotal power, just as the diphtheria antitoxin has? I am aware that "one swallow does not make a summer," and that arguments based on one case are not weighty, so I send this brief history hoping that others of your readers may have had one or more cases of mumps develop in the course of articular rheumatism, and that they may be willing to give their testimony for or against this hypothesis of antidotal effect.

TRANSPOSITION OF VITAL ORGANS.

By S. J. SOMBERGER, M.D.,
CORTLAND, N. Y.

On February 5, 1900, Mr. W——, aged twenty-three years, came to my office to be examined for life insurance. I found the heart with its base situated about in the normal position, but with its apex inclined toward the right side, the apex beat being at about the same point on the right side as we usually find it on the left. The liver dulness is absent on the right side, and its place is occupied by normal lung resonance. In the nipple line the lung extends down to about the costal border. The liver dulness is found to the left of the median line and slightly lower than the usual position. The right testis hangs lower than the left. This seems to be a case of complete transposition of organs. The man appears in perfect health.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-fourth Regular Meeting, held Friday, March 2, 1900.

A. ALEXANDER SMITH, M.D., PRESIDENT, IN THE CHAIR.

A Case of Bradycardia.—This was presented by DR. E. G. JANEWAY. The patient was a young man, a soldier by occupation, whose usual pulse-rate, for several years past, had ranged from 30 to 36 per minute. It sometimes dropped as low as 20 and occasionally rose to 60. No satisfactory cause for the bradycardia could be elicited. When the patient was eight years old, he had an attack of diphtheria, from which he apparently made an uneventful recovery. He had never had rheumatism or scarlet fever. He had never smoked. The heart was large; its action was slow and forcible. A faint aortic and mitral systolic murmur could be made out. There was no suspicion of arterial sclerosis. There was no acceleration of the pulse upon exertion. Occasionally a faint accessory pulsation could be detected at the wrist. At the age of twenty, on entrance to the army, the pulse was 100; at twenty-one it was 90 when nervously excited; at twenty-two it was 84; and at twenty-three it had become 38, slow and strong, without disease intervening. The patient stated that when his pulse rose to 60 per minute, as it occasionally did, it might maintain that rate for several hours or only for a few minutes, and during those periods he felt comfortable. When it dropped back to its usual rate, however, he felt very uncomfortable on account of the long intermissions. When the beat occurred, there was apparently a rush of blood to the head, giving rise to headache and dizziness. When the beats fell as low as 20 per minute, syncope might result. Numerous cardiac stimulants had been tried without effect: some of them made the heart beat harder, but no faster. Application of mustard to the neck, with the idea of stimulating the sympathetic, had also been unsuccessfully tried. Inspection of the chest and palpation made out a slight pulsation of the heart between the stronger beats. At times two such beats, one extremely feeble, could be detected. The cardiogram prepared by Dr. T. C. Janeway showed the same. The carotid tracing exhibited this to a less degree. The sphygmogram of the radial showed no extra beat as a rule.

Dr. Janeway, in reply to a question, said he thought there was some thickening of the aortic valves, a slight leakage at the mitral, and perhaps myocarditis.

DR. GEORGE L. PEABODY referred to a case of bradycardia which was reported to the society some years ago by Dr. Ball. The patient was an elderly lady in whom the slow pulse persisted for years, and during that time she failed in general health and had attacks of syncope. She was over eighty years old, and gradually senile symptoms developed until she failed to recognize even members of her own family. Without any special treatment, the heart's action improved, the pulse rate increased to 60 and 70, and this was followed by a clearing up of her mental symptoms and she again became bright and cheerful. Dr. Peabody said that usually the slow pulse was associated with arterial sclerosis of the coronary vessels, but that when we remembered how common this lesion was and how rare was this symptom, the association between the two was hardly apparent.

The president, DR. A. ALEXANDER SMITH, reported a case of bradycardia seen in consultation in which the pulse rate fell as low as sixteen beats per minute. The patient was a man seventy-three years old, with arterial sclerosis and, apparently, myocarditis. He had a systolic murmur at the apex and a very rough systolic murmur at the base. He had always led an exceedingly active life. About a week ago he visited the office of a physician who lived near by, and while there he had a convulsive attack and lost consciousness. When he returned to consciousness he was somewhat delirious, and there was a partial loss of power on the left side of the body which soon cleared up. He was carried to his own house and put to bed, and remained delirious for several days. He was able, however, to impart the information that for the past five years he had known that his pulse rate was slow—about 40 per minute, and occasionally dropping to 38 and 36. He was suffering from interstitial nephritis, which had developed to a moderate degree, and there was some arterial sclerosis. The heart and pulse beats were entirely synchronous. Since his attack in his physician's office a week ago, the patient, in addition to his delirium, had been extremely irritable. Several times his pulse had fallen as low as 16 beats per minute, and then gradually gone up to 28 or 30.

A Case of Suffocating Laryngeal Papilloma.—This case was presented by DR. ROBERT ABBE. The patient was a girl thirteen years old, who was first brought to him at the Post-Graduate Hospital in 1892, suffering from an obstructive condition of the larynx which had rendered her cyanotic and comatose. The trachea was at once opened, and the child's condition immediately improved. The larynx was found to be filled with papillomata. Subsequently, Dr. Abbe made a vertical section of the larynx and removed at least a teaspoonful of these growths. The child made a good recovery, and the wound was allowed to close. In two months there was a recurrence; the larynx was again opened, a complete laryngotomy being done, and a considerable mass of papillomatous tissue removed. The actual cautery was then applied to the base of the growths, and everything that was likely to produce a recurrence was apparently destroyed. In spite of these precautions, a second recurrence took place within a few months. The larynx was again split and the papillomatous growths were removed. Monochloracetic acid was then applied to the base of the growths, and the child was allowed to breathe for a time through the tracheotomy tube. Again a recurrence took place, and again the growths were removed and the site from which they sprang was cauterized—this time with carbolic acid. The tracheotomy tube, which had been left in only for brief periods after the previous operations, was now left undisturbed for six years. It was removed last year, and up to the present time there had been no signs of a further recurrence. The child was in good health, but her voice was necessarily impaired by the fact that some of the growths involved part of the vocal cords; she was only able to speak in a whisper. Previous to the last operation, the tracheotomy tube was replaced for a time by an intubation tube, but the child did not derive much benefit from it. The idea in leaving the tracheotomy tube in place for so long a time was to give rest to the larynx. Cases were on record, Dr. Abbe said, in which the prolonged use of a tracheotomy tube had apparently prevented the recurrence of papilloma in the larynx.

DR. BEVERLEY ROBINSON said the rest afforded to the larynx by the prolonged use of a tracheotomy tube probably modified the tissues of the interior of the larynx. This was the explanation given in those cases in which a cure had apparently been effected by this means.

A Case of Extensive "Hairy Mole."—DR. ABBE showed this case. The patient was a boy three years old, with a hairy mole which covered a considerable portion of the left side of the face. It embraced the entire cheek, most of the nose, both eyelids, the temple, and half of the forehead. The skin of the lesion was hypertrophied, deeply pigmented, and covered with a growth long of hair. The child's mother attributed the deformity to a maternal impression received during the third month of her pregnancy, when a boy, in play, brought a dead rat to her, and whirling it round his head struck her with it. Dr. Abbe said that on account of the disagreeable appearance of the deformity in this case, the parents were very anxious to have something done, and he thought that even a surgical scar would be preferable. He intended to shave off the pigmented layers of the skin, going down as deeply as was found necessary, and then to apply skin grafts by Thiersch's method.

Dr. Charles Stedman Bull said that any operation upon the external surface of the lids, even by Thiersch's graft method, would probably tend to produce an ectropion, particularly of the lower lid. Cauterization of the lesion would be even more apt to produce ectropion than skin-grafting. Dr. Bull said he did not think there was the slightest danger to the eye itself from any proposed operation on the lids.

Pneumothorax Occurring in Persons with Apparently Healthy Lungs.—This paper by Dr. Walter B. James detailed the history of three cases in which the symptom occurred after severe exertion and without any demonstrable lung lesion. In all recovery took place in comparatively short periods.

Dr. Janeway said he had met with five cases like those described by Dr. James. One of the cases, which he saw last summer, was that of a young man, who, after rapidly running up five flights of stairs, was taken with a severe pain in the chest. The pain was thought to be due to heart trouble. Dr. Janeway saw him two days later and found a pneumothorax, from which the patient made a good recovery in about a month. In another case, that of a young man eighteen years old, the perforation of the lung also occurred after a good deal of exertion. In that instance, Dr. Janeway said, he suspected that a small nodule or emphysematous bleb had given way. Occasionally, around a fibroid nodule, there might be a compensatory emphysema which might give way. In all of the cases which had come under the speaker's observation, complete recovery took place: in none did fluid occur, and in only one did he suspect a coexisting phthisis. Even in phthisis we might have a pneumothorax without the presence of fluid. The condition of pneumothorax was a comparatively rare one, and the prognosis was good. In one of his cases the patient was a woman who suffered from bronchitis and emphysema, and during a severe fit of coughing a pneumothorax developed. She made a good recovery.

Dr. H. M. Biggs said he had seen two cases of pneumothorax in hospital practice. Both patients made a good recovery in a short time. The speaker said his impression had always been that while in these cases there might not be any demonstrable lesion in the lung, the perforations took place at some point of the lung where the resistance had been diminished by some pathological process.

Dr. Beverley Robinson said he had seen one case of this kind, and had attributed the perforation of the lung either to the presence of a tubercle on the surface or to the bursting of an emphysematous vesicle.

Dr. Peabody narrated the following case, which occurred during his student days in Vienna. The patient was a little girl who swallowed some caustic potash, producing a stricture of the œsophagus which was being dilated by sounds. The passage of these instruments gave rise to severe coughing fits. In the course of time she learned to pass these sounds herself. During one of her coughing-spells induced by the passage of the sound there was a sudden collapse of the lung. From this she recovered, but the accident happened again some months later and caused her death, in syncope. In the diagnosis of pneumothorax, Dr. Peabody said, he would suggest the use of the hypodermic needle as a corroborative sign, just as it was employed in pleurisy with effusion. In the second case reported by Dr. James, Dr. Peabody said the chest could not have been filled with air because the heart was not displaced. It could have been only partially filled.

Dr. James said that in neither of his two cases were there any symptoms or evidences of tuberculosis. In the first case there was not even a suspicion of it. In the second case the disease might possibly develop later.

Dr. Robert F. Weir said he wished to say a word about the cohesion of the lung to the chest wall. Many years ago he witnessed some experiments made by Dr. A. H. Smith on animals, and they demonstrated very clearly that when the opening in the chest wall was made over one of the lobes of the lung, cohesion continued, but if, on the contrary, the opening involved one of the clefts between the lobes, immediate collapse of the lung took place. This observation he had since corroborated in several cases in which in operative procedure the pleural cavity had been moderately opened. Dr. Weir said that in certain cases of pneumothorax, in which there were symptoms of overdistention, it was perfectly proper to relieve the pressure by opening the chest cavity. It might occasionally be necessary to do this in order to save life. The speaker recalled one such case, in which, while removing some enlarged glands from the deeper tissues of the neck, he accidentally opened the pleural cavity without knowing it. The patient began to breathe heavily and was almost moribund before the cause of his condition was made out. The chest was then punctured, with a great outrush of air, but the patient was too far gone and succumbed. A second analogous case had since then come under his care in which similarly the neck wound acted valvularly, allowing air to be sucked in but none to escape. Here a chest incision was made and the patient recovered. Dr. Weir said it was also considered justifiable to open the chest wall for the arrest of a persisting and dangerous traumatic pulmonary hemorrhage. The lung collapse in this instance brought about pressure on the damaged vessels.

Dr. Janeway said experimentation had shown that under pressure air could be forced through the pleura and even through the veins. After such experiments, air bubbles had been found in the pleural cavity and in the left heart. This had been suggested as one of the causes of sudden death.

Dr. Biggs said that some years ago he reported a number of cases in which exploratory puncture of the chest had been followed by pneumothorax, and in some instances by death. In one case a double pneumothorax followed exploratory punctures: this was proved at autopsy. In two cases which he saw at autopsy, the needle-puncture of the lungs could apparently be seen.

A Case of Diabetes in a Child with an Unusual Family History.—This case was reported by Dr. A. Alexander Smith. The patient was a well-nourished boy, twelve years old, who was born in Colorado, at an elevation of five thousand feet above tide-water, and had always lived there. His parents were alive and apparently in good health. The boy was brought to New York last November by his mother, a very intelligent woman, who stated that his urine had been known to contain sugar for at least the past four years. She also said that she had lost one child, about four and one-half years old, of diabetes, the disease proving fatal in two years: also another child, a daughter, aged seven years, of the same disease, lasting in that case three years. She then found, upon investigating the family history, that her husband's father had had diabetes for fourteen years, and that his sister—a great-aunt of the boy who was brought to New York—had suffered from diabetes when she was sixty-five years old. The boy's father had apparently escaped the disease. There was also a rather uncertain history of diabetes in one of the mother's ancestors, namely, a sister of the mother's grandmother. An examination of the boy's urine upon his arrival here showed the presence of considerable sugar. Without any medication and with only a partial restriction of his diet the sugar steadily decreased in amount, and after a few weeks it disappeared entirely. Dr. Smith said he attributed the improvement to the change of residence, and he advised the child's mother not to take him back to the high altitude where his disease had developed. The family to which this boy belongs, Dr. Smith said, were not Hebrews. The frequency of diabetes in that race was well known. The speaker said he was familiar with one Hebrew family, three members of which were suffering from this disease. He suggested the possibility of some causative relation between the high altitude and the development of diabetes in some instances. The influence of the altitude on the nervous system might possibly be a factor in the production of the disease.

Dr. J. W. Brannan said that during a four years' residence in Colorado, at an elevation of six thousand feet, he examined many specimens of urine, and while there were numerous cases of albuminuria, he could not at the moment recall a single case in which the urine contained sugar. He remembered, however, one case of diabetes insipidus which came under his observation in Colorado in 1880. The case was that of a physician who had two uncles in an eastern State who were sufferers from diabetes mellitus. The patient himself had simple polyuria, accompanied with excessive thirst. He had a phthisical history and was also rheumatic, and recently some rather obscure mental symptoms had developed.

Dr. Robinson said he had a patient whose urine contained sugar when he was in the city, but when he went to the country and was free from business worry, the glycosuria entirely disappeared.

Dr. Janeway said he did not think the altitude had anything to do with the diabetes in the case reported by Dr. Smith.

Dr. Smith said this boy's mother had noticed some time ago that when he was taken to a lower altitude than that of his home, the quantity of sugar in the urine diminished.

Skiagram of Œsophageal Stricture.—This was exhibited by Dr. Robert Abbe, in connection with the following case. The patient was a married lady, who, since she was sixteen years old, had suffered from great difficulty of swallowing. The obstruction was so pronounced that she almost died from inanition. Her trouble was due to a congenital stricture of the œsophagus at the level or the diaphragm, and just above this there was a pocket or diverticulum into which the food which she swallowed would pass. A gastrotomy revealed a minute, atrophied stomach, and extending upward a short tube which represented the lower portion of the œsophagus.

A Case of Chyluria.—Dr. Francis P. Kinnicutt exhibited (through Dr. Weir) a specimen of urine from a case of chyluria or hæmato-chyluria. It had the appearance of milk of a good quality. The patient was a woman who was admitted to the Presbyterian Hospital suffering from a lobar pneumonia which ran a mild course, and from which she made a perfect recovery. The chyluria appeared ten days after convalescence was established. The patient presented no other symptoms of any kind, and physical examination at present was absolutely negative. The urine was free from casts, contained blood discs, and no more albumin than was accounted for by the blood. It also contained a moderate number of leucocytes and fat in a molecular form. From time to time she passed urine entirely free from blood. The patient's blood had been examined a number of times, the specimens being taken both at night and during the day, and none contained the filaria sanguinis hominis. Dr. Kinnicutt said that these cases of non-parasitic chyluria were of very rare occurrence.

A Case of Sudden Death.—This case was reported by Dr. J. W. Brannan. The patient was a laborer, forty-nine years old, who had been an inmate of Bellevue Hospital more or less constantly since October, 1898. His family history was negative. Personally, he was a hard drinker and smoker; he had rheumatism twenty years ago, but denied syphilis. He never had had any cardiac symptoms. About one year previous to his admission to the hospital he began to suffer from shortness of breath, and his feet became swollen at night. The shortness of breath gradually became more pronounced, and he grew weaker. When he entered the hospital, his symptoms were limited to the heart and kidneys. He was decidedly cyanotic; the heart's action was irregular and intermittent. The apex beat was in the sixth intercostal space, outside the nipple line. There was a soft, blowing systolic murmur, transmitted to the left. The urine contained albumin and casts. Under the administration of cardiac stimulants his condition improved and the murmur disappeared, occasionally reappearing without any assignable reason. Later on it disappeared permanently and was replaced by a pre-systolic murmur which was also inconstant. The patient then left the hospital for a time, and was readmitted about a month later. He was then troubled with a severe bronchitis. There were no signs of any valvular lesion. The bronchitis gradually improved, but three days ago, while he was resting quietly in bed, he suddenly died without any apparent cause. The autopsy showed a large heart, with dilated cavities and thickened walls. The heart muscle was pale and flabby. There was no affection of the coronary arteries, excepting that they were somewhat thickened. They were pervious throughout. The mitral valve was constricted, admitting but one finger. Otherwise the heart was normal. It weighed between eighteen and nineteen ounces. An examination of the brain showed a chronic leptomeningitis on both sides, but nothing else. There was no embolism. The kidneys showed the lesions of a chronic diffuse nephritis. Their surfaces were roughened and the capsules adherent. Each weighed between seven and eight ounces, about one-half as much again as the normal kidney. Dr. Brannan said he could assign no satisfactory cause for the sudden death in this case, unless it could be attributed to acute dilatation of the heart. The cavities were large and filled with blood. The post-mortem specimens in this case, which Dr. Brannan exhibited, had not yet been subjected to a microscopical examination. In reply to a question by Dr. Janeway, the speaker said that the patient was receiving no medication whatever at the time of his death. The case was one of a type not infrequently seen in the class of patients admitted to Bellevue Hospital. The man had lived a life of hard work, exposure, and strong drink, and the time came when the heart simply gave out, though not at the moment under any unusual strain.

Cardiac Dropsy.—Calomel, gr. $\frac{1}{5}$, should be given every two hours for four or five days; then combined with small doses of digitalis leaves, gr. $\frac{1}{4}$ to gr. $\frac{1}{3}$.—Finkelstein.

(From our Special Correspondent.)

MIDWIVES BILL—RUPTURE OF ŒSOPHAGUS—SARCOMA OF GASTRO-HEPATIC OMENTUM — CHEMISTRY OF GOUT — DISINFECTING WATERWORKS — DEATHS OF DRS. MIVART, JACKSON OF UGANDA, DICKSON, AND GUNNING.

LONDON, April 6, 1900

THE midwives bill is by no means dead. It is giving signs of even more vigorous life. It will probably not come before the House of Commons again until after the Easter recess, but then a determined attempt to force it through will be made. Many members of the profession have lately waked from their apathy and begun to realize the danger. Accordingly they are blaming the Medical Council and the corporations for giving it a qualified sanction. The promoters have eliminated the safeguards and shamelessly told the committee that these bodies support the bill. They are trying to prevent penalties and to protect all the ignorant women who have called themselves midwives—in fact to establish them as independent practitioners. If they succeed we may look for great injury to the public, and there are dangers which ought not to be forgotten in trusting this class of women with midwifery practice.

The meeting to protest against the bill was held on Wednesday, when Mr. George Brown presided. He showed that the bill would authorize only the incompetent, whereas the opponents desired that all women allowed to practise should be educated and qualified. Resolutions condemning the bill were unanimously passed. The meeting then rapidly thinned—the number falling from nearly one hundred to seventeen or eighteen, or certainly under twenty. A resolution was brought forward asking Dr. Glover to resign his seat on the Medical Council and appeal to his constituents to re-elect him. Mr. Brown before this had vacated the chair, and Dr. Toogood took his place. There was some difference of opinion as to whether this would be in order, and whether it would be advisable considering that so large a majority had left before the subject was broached. Eventually the resolution was carried. You should understand that it is solely on account of the position he has all along held on the midwives question that Dr. Glover has given umbrage to a large and increasing section of his constituents. In every other way he retains their confidence, and he is universally esteemed.

Rupture of the œsophagus is so rare that only sixteen cases seem to have been recorded as such, though others have almost certainly been related under different names. A case was described at the Medico-Chirurgical Society by Messrs. Bowles and Turner in a woman aged sixty-two years, who in vomiting was suddenly seized with collapse and severe epigastric pains. Vomiting ceased; emphysema of the neck came on, extending to the face, and she sank in twenty-two hours. The post-mortem left no doubt that the rent occurred before death; it was longitudinal and one and one-half inches long. Some remarks were made on the diagnosis of this lesion and its possible treatment by surgery. Drainage of the posterior mediastinum and suture of the rent were suggested. Some similar cases were mentioned, including two in the Pathological Transactions, which were attributed to post-mortem softening, but which were very likely rupture. The clinical history has to be considered. In this case it was said the pulse was only 50, but the arterial tension was maintained in spite of collapse. It was thought irritation of the vagi might explain this. Dr. Rolleston remarked that the rupture was always in the lower third, although the weakest part was at the junction with the pharynx, and he suggested this might be because the lower third is composed of smooth muscular fibre only. He thought rupture was often preceded by a small ulceration which was concealed by the rent. Mr. Turner had made some experiments, and could not think ulceration necessary; he was surprised how easily rupture was produced, and it was always longitudinal and in the lower third. A case was also related at the Academy of Medicine in Ireland, by Professor McWeeney, who showed the specimen. A workman aged forty years, an alcoholic, after retching violently, was seized with extensive emphysema of the face and neck and died in a few hours. At the post-mortem the rent was found one-half inch long just above the diaphragm.

Mr. Pearce Gould showed a man aged thirty-eight years, from whom he had removed a spindle-celled sarcoma of the gastro-hepatic omentum four and one-half years ago. The tumor weight twenty-one pounds, and was also shown with some sections. He had found only one other such case. The chief clinical feature of tumors of the small omentum is the pushing down of the stomach and so obscuring its resonance, which may reappear below. There is also great elongation and displacement of important structures without such definite grave symptoms as might be expected.

There were two papers on gout at the Medical Society's meeting. The first was by Dr. Luff, who corrected a misapprehension in some quarters of an article of his which called in question the solvent action of certain drugs, but did not deny their utility. Dr. Luff is an able chemist; he was a teacher of chemistry before he was a medical student, and naturally brings his special knowledge to work on clinical material now that he is a hospital physician. His present paper is on the bearing of the gelatinous form of sodium biurate on gout. He holds, as did Roberts, that the deposition of quadriurate, at first gelatinous in form, becomes crystalline and almost insoluble, thus setting up a gouty paroxysm. If the change from gelatinous to crystalline form can be delayed, the gouty attack can be postponed. Now the conversion is accelerated by sodium bicarbonate but delayed by potassium bicarbonate, which also retards the process after it has started. Lithium does not delay the initial change, though it retards it when started. Piperazin does not delay the initial conversion, though it slightly retards it when started. Lysidin delays the initial conversion, but when once started has no effect. Thus it would seem that the potassium salt is best, and the lithia next, while piperazin and lysidin are inferior; and these results accord with Dr. Luff's clinical experience. Not that he would gauge the value of alkaline salts solely by their solvent action on deposits of sodium biurate, or by their inhibitory action on the conversion of gelatinous into crystalline forms of biurate. He admits they may be useful by stimulating metabolism, acting on the stomach, liver, and kidneys and reducing the acidity of the urine. An important fact which Dr. Luff claims to have established is that the higher the alkalinity of the blood from sodium bicarbonate the more rapid and the more complete is the conversion of the soluble gelatinous into the comparatively insoluble crystalline biurate. He holds that the alkalinity of the blood in gouty patients is higher than normal. In the blood of healthy adults he found an average of 0.185 per cent. of sodium carbonate, and in the gouty this rose to 0.217 per cent., an increase of nearly one-third. It would seem therefore that we must dismiss the notion of an "acid dyscrasia." The inference from all the experiments is that increased alkalinity determines the gouty paroxysm.

The second paper was by Dr. Bain, of Harrogate. He related observations made to determine the variations in nitrogenous elimination in a case of gout under ordinary conditions, and the effect of diet and drugs. After sodium salicylate a slight increase of uric acid was noted, but under guaiacum there was a marked increase of this acid, and vegetable diet also increased it. Iodide of potassium increased both uric acid and urea. Referring to Minkowski's experiments it was suggested that one or more of the alloxur bases might be concerned in the evolution of gout; for one of these bases, adenin, had been followed by violent action of the heart, vomiting, increased blood pressure, while the urine contained leucocytes, albumin, casts, and epithelial cells. Post-mortem crystals of biurate were found in the renal tubules. Uric acid does not produce such effects and possibly may be relegated to a secondary place as a cause of gout.

Dr. Sims Woodhead and Mr. J. W. Ware described to the Society of Engineers on Monday the plan they had adopted to disinfect the water-mains at Maidstone after the typhoid epidemic three years ago. On a Saturday night the water-service was shut off except from a small portion reserved to be treated separately. Chloride of lime was mixed with the water in the reservoirs and forced through the mains until the flow from the house taps became milky. Then the mains were emptied with five engines, the reservoirs thoroughly cleansed, and pure water was then sent through the whole service. The work occupied twelve hours, the mains being sixteen and three-quarter miles long, with a capacity of one hundred and eight thousand gallons.

Dr. St. George Mivart died on Sunday, aged seventy-two years. His "Genesis of Species" controverted Darwinian views, and he kept a close hold on the attention of a large section of scientists by his biological and other contributions to literature. He joined the Roman Catholic Church in 1884, but his independence of view in treating scientific questions offended the priestly party, and about two months ago Cardinal Vaughan peremptorily ordered him to sign a confession of faith. On his declining to obey the cardinal served his clergy with orders to refuse the sacraments to the aged invalid scientist, who thus suffered all the persecution that the Roman Church can inflict on her adherents in this age and country.

Dr. Dickson, who has been physician to the British embassy at Constantinople since 1856, died on Tuesday, the 27th inst., at an advanced age.

Dr. H. C. Jackson, of the Uganda service, succumbed to fever on February 16th in his thirtieth year. He had achieved a considerable position by his work in the Protectorate.

The death is also announced of His Excellency R. H. Gunning, M.D., LL.D., Edinburgh, Grand Dignitary of the Order of the Rose of Brazil. He founded eleven Victoria Jubilee prizes in Edinburgh University and the Cullen scholarship of the College of Physicians. Of late years he was quite blind, but bore his affliction bravely and took the greatest interest in scientific progress and current news. He died on the 22d ult., aged eighty-one years.

Hernia in Children.—Operation is advised (1) in children over four years of age in whom a truss has been given a fair trial without marked improvement. (2) In cases complicated with fluid in the hernial sac (reducible hydrocele); in all cases of femoral hernia, since this form of hernia offers little or no hope of cure through mechanical treatment. The practice of operating upon infants under one year of age or even two or three years is, I believe, open to serious criticism.—W. B. Coley.

LETTER FROM CONSTANTINOPLE.

(From our Special Correspondent.)

TURKISH MEDICAL SCHOOLS — REFORM IN PUBLIC HEALTH ADMINISTRATION—DEATH OF DR. DICKSON.

There are three medical teaching establishments in Turkey, one at Constantinople, "The Imperial Faculty of Medicine," Turkish; and two at Beyroot in Syria, American and French. Recently a delegation from the Imperial Faculty of Medicine of Constantinople was sent to Beyroot to assist at examinations for the doctorate of the French school. This delegation was presided over by Haireddin Pacha, and it is understood that his excellency, on his return, has presented a report in favor of establishing an Ottoman school of medicine at Damascus or Beyroot (probably Damascus), for the consideration of the minister of public instruction.

The medical teaching at the American college is simply an outcome of the general progress of the course of education, and is admitted to be good. It has sent forth some fairly well-trained men, who, though holding the diploma of the school, must pass an examination at the Imperial Faculty of Medicine before being permitted to practise; as must also all foreigners. The French Medical College is of more recent date, and doubtless the teaching is on a level with that of the American. This projected medical school at Damascus may possibly be associated with certain other projects of reform being carried out in the medical service of the empire, if it be not inspired by jealousy and as a set-off against the other schools. Otherwise there would appear to be an overlapping of medical institutions.

The medical school of Constantinople was established in the reign of Sultan Mahmoud, 1838 or 1840, under Austrian administration, and for several years was successful in turning out a class of medical practitioners superior to the barber-surgeons of the day. Difficulties, however, arose about the teaching. Confusion of tongues and want of text-books in the Turkish language, religious feelings, which discouraged dissection of the dead, had to be taken into consideration. Hence, for a time, the scheme for improved medical teaching languished, though it was continued on the improved basis until the present day.

Like most Turkish institutions, the school had a brilliant short period, then a lapse of indifferent régime, reformation, reconstruction, and so on periodically; depending upon the amount of imperial support and the solicitude of the army direction. Although the school may not have given the results expected by its founders, yet it has provided a better class of army and navy doctors, which was the original intention.

Located at first in Galata-Serail, it was liberally provided with library, museums, horticultural garden, amphitheatre, and anatomical cabinet, and being the first scientific institution of the country, it became an object of great solicitude to the sovereign. In 1848 Galata-Serail was burned down and all its scientific riches perished. The school took refuge in a building in the Golden Horn, and for a period of seventeen years was almost forgotten, though its work was continued. Then again a revival, and progress, until the time it was transformed into a faculty, with very considerable powers. During the past ten or twelve years there has been a steady improvement in the teaching of the faculty, and as many of the students were sent to the higher continental schools of medicine a certain number of good class surgeons and physicians have been produced.

It is now proposed further to extend and improve the medical teaching, especially in relation to the army and navy, and an extensive and imposing army medical school, with modern improvements and appliances, is in course of construction (nearly finished) at Haidar Pacha on the Asiatic shores of the Bosporus. To this will be added a bacteriological institute, an antirabic establishment, etc. The reforming process has been entrusted to Dr. Rieder Pacha, a German officer in the Turkish service. It includes a course of German, botany, chemistry, physics, and natural history, and apparently it is intended to use German as the medium of teaching, for in the instructions it is stated, "As there exist many works on medicine in German, the administration of the military schools is enjoined to give particular care to the study of that language." The pupils of the faculty of medicine will, after two years, attend the Haidar Pacha school. The scheme presupposes a preparatory school, which already exists and is included in the reforms.

It will be interesting to watch the progress of the new departure, in which his imperial majesty the Sultan takes deep interest, as indeed he does in all matters of education. There will be certain difficulties to overcome, as of old. The selection of a foreign language as the medium of teaching is an important one, as former experience has shown, and one cannot but think that the natives of a country would be better taught in their own tongue, and so be more in touch with their teachers.

In matters of public health also, Turkey is in a spasm of reform; new regulations of the Council of State, sanctioned by Imperial *iradé*, have been promulgated with regard to the examination of foods, drinks, chemical and pharmaceutical specialties. A chemical laboratory is to be established at the custom house, at which five chemists and two doctors are ordered to be on service. Of the twenty-four articles of the regulation, those applicable to drugs may be quoted: "The following specialties, the use of which are recognized as hurtful, *i.e.*, cocaine and its compounds, sulphonal, anti-tuberculous serum of Dr. Koch, picrotoxin of Gneiss—that is to say, specialties prepared from haschish—are prohibited. The entry of articles such as chlorate of potassium, nitrate of sodium, nitrate of potassium, chlorate of sodium, and picrates, is forbidden, and they will be confiscated.

"The following drugs comprised among the articles prohibited, but of which the use in medicine is obligatory, such as chlorates of potassium and sodium, etc., will be furnished through the agency of the grand master of artillery at their original prices, and in quantities fixed by the Imperial School of Medicine for each pharmacy and each *ahtar* (druggist).

"However, the entry of pastilles of chlorate of potassium and other analogous preparations, in form of specialties, which cannot be employed for the preparation of explosives, is permitted."

It is also proposed to create a bacteriological establishment at the international health board, with a highly paid professor—a somewhat costly scientific luxury—the purpose of which is not very evident. These and other regulations of municipal hygiene of the most elaborate character are the order of the day. But—and alas!—they are likely to be paper plausibilities, inasmuch as they are costly in practice, and money is not now an abundant article in Turkey.

A notable presence in the medical profession has passed away. Dr. E. D. Dickson, physician to the British embassy, and British delegate at the Ottoman health council, died yesterday. A highly educated and courteous gentleman of the old school, an accomplished physician, an excellent linguist in Eastern and Western tongues, a charming raconteur, he was esteemed by all classes. He had reached the ripe age of eighty-seven years. He was well known for his genial courtesy to his American colleagues who visited Constantinople.

THE USE OF ARSENIC, ETC., IN CANCEROUS AND OTHER MALIGNANT NEOPLASMS.

To the Editor of the Medical Record.

Sir: In a recent article by my friend and colleague, Dr. A. R. Robinson, of New York, appearing in the Medical Record of March 31, 1900, entitled, "Observations on the Treatment of Cancer," I am prominently mentioned as favoring the internal use of arsenic in all cases of cancer—an assertion which, while it does not misstate facts, it being unqualified, leaves my position open to the inference that I rely upon the internal use of this remedy alone, to the exclusion of other and more radical primary surgical procedures. So far is this from being so, that I wish to say right here, that I can unhesitatingly indorse the author's valuable paper in its premises, tenor, and conclusions (all of the latter save one), and in his criticisms on those who are inclined to rely on the knife, and that alone, for relief or cure of those maladies. I will also add that as a medical contemporary of the doctor I believe I have as long, as earnestly, though probably not so ably as himself, used, advocated, and defended the employment of escharotics in the treatment of these malignant tumors, as my colleagues of the American and New York dermatological societies can testify, in the many years of my membership.

It may be as well to say now that the caustic I have used most and which is my chief reliance at present is the acid nitrate of mercury (fifty-per-cent. solution). I employ it for the exact reasons which Dr. Robinson claims for his arsenical pastes, viz., first, as to its having in my belief a certain elective, destructive activity on the pathological tissue, far beyond the sphere of its escharotic action; and also, second, to my mind a greater facility in handling; and third, its easy management by those having any experience as to its rapidity and extent of destruction of tissue, etc.

As a preliminary to application of this caustic I use either knife, or curved scissors, or curette to take away the redundant mass of the tumor or fungating ulcer, etc.; usually, however, much preferring the curette energetically employed. Then after mopping the tissues needing it with a twisted pledget of cotton dipped in the fluid once, twice, or many times, according to circumstances, I allow it to remain any length of time from five to thirty minutes; this is where experience and frequency of this operative method naturally come in; after such time I neutralize with bicarbonate of sodium, leaving a layer of that salt on as a dressing. Nothing further then remains to be done except to await the falling of the blackened dry eschar, occurring at any time from eight to fifteen days, which leaves ordinarily an almost healed or quickly healing surface to be treated as any other open wound.

I think Dr. Robinson will excuse me if I here make a transcript of his conclusions, six in number, given at the finish of his valuable paper, the whole of which, excepting absolutely No. 1, I look upon as aphorisms. My experience and reasons as stated allow me at least to question the accuracy of the first:

"Conclusions.—1. At present we know of no drug, animal extract, serum, or toxin, which, given internally by any avenue of the body, can be relied upon for the cure of cancer of any part of the system.

"2. That the statement that the knife is the only reliable agent in the treatment of cancer is not correct.

"3. That certain caustics judiciously chosen and properly applied may attack deposits of the growth inaccessible to the knife, and in these cases should be employed even if the knife is necessary to prepare the way for their use.

"4. That in some cases both the knife and caustics should be used, and in some other cases curettage, followed by a caustic, is the proper procedure.

"5. That the majority of cases of cutaneous cancer can be removed with the greatest certainty and with least deformity by caustics, provided the patients are seen before the lymphatic glands are invaded.

"6. That the knife should be used when the lymphatic glands are invaded, and also in some other cases of external cancer."

The doctor's destructive agent is, as will be noted, an arsenical preparation, and he speaks (p. 538) "of its specially selective antagonistic action on the epithelia in this disease." I believe this proposition he states as being unquestionably a fact; but how, then, is he to escape the rational inference that arsenic administered internally would not have in a certain degree the same, though perhaps lessened and modified, action? I do, as aforesaid, so believe, and in the short bibliography of my own papers annexed would point to proof of its action not alone on epithelial structures, but also on those of the kako-plastic, nonviable fibrous neoplasms we call sarcomas. I am not unmindful either of the destructive action of inflammation on these errant and aberrant cells, and believe it to be great and beneficial, therein excelling the knife; but must insist that the preparation I use acts in much the same way as his, and I think with at least equal power, as it is not only absorbed from the raw surface to which it is applied, but finds its way along the lymph channels of the adjacent skin. It is a common occurrence with me to see slight ptyalism result under my method of treatment in wounds of less than a fifty-cent piece in area, and this is sometimes quite severe in cases of a larger circumference —a thing itself, however, that never causes me the least anxiety, and, from the very nature of things, it quickly subsides.

I begin to give arsenic, usually Fowler's solution (sometimes one-fifth of the quantity given will be Donovan's), the second or third day after operation; I do not want to bother the patient too much at the time. The pain of the operation is generally severe at first, but can be modified and subdued by the usual means (too long and commonplace to treat of here), but my method, as it seems to me, has this advantage over the arsenical pastes, that the pain in my procedure is greatest at first contact, then gradually lessens, which I think is entirely the reverse in the use of the pastes; at least it has been so in my employment of them.

One more criticism of this paper which I so much admire, and I have done; and that is this. When I have cooked the seat of the affected tissues sufficiently I can leave the patient, knowing that beyond a resultant irritant inflammation of that and the near surrounding tissues, which inflammation, by the way, I have never found dangerous, I have finished. It does not seem to be so with these pastes, however beneficently they may act otherwise. This fact may be due to idiosyncrasy, peculiar susceptibility of tissue, or what not; but the fact remains that in using the same paste, one which will in one patient hardly cause anything but a superficial eschar will in another case cause gangrene of tissue of the highest grade, and therefore needs, as the doctor says, careful and diligent watching.

One bad result of an arsenical application will always remain in my mind; it was applied by a past master of this form of treatment, and one I know to be very successful ordinarily; it caused excessive destruction of tissue in a most unfortunate location, and yet the patient had obeyed instructions *au pied de la lettre*, the excessive and increasing agony only leading to removal of the applied plaster an hour or little more before instruction to do so. I have also seen pastes apparently penetrate unbroken and seemingly at least sound epithelium, almost or quite as readily as tissues that were evidently disorganized.

The second, third, and fourth clauses in Dr. Robinson's conclusions I believe to be eminently sound and true, at least in proper hands; as to the fifth I am equally certain. There are many points he brings out in support which I will not touch upon; but to one, not usually considered, I must refer, agreeing with him as I do—and that is, that the occurrence of a fair amount of granulation tissue after a procedure like his and mine tends to improve the cosmetic effect by rendering the depression less marked; and that ordinarily about the face in particular the resultant effect is extremely good. It is astonishing often to see the slight scar deformity where one would have expected under any procedure to have had great disfigurement. As to clause No. 6, I here again agree with him in gender, number, and case. Certain tumors, perhaps most of those of the lips, penis, and ears, may and can be most efficiently treated by the knife, or combination of methods.

I may add in conclusion that I operate and have done so in hospital and private practice fairly frequently; my cases must, I think, run into the hundreds now. Since commencing this paper two or three days ago I have operated three times on epitheliomas of the face, in the persons of two men and one woman; the woman and one man are aged about sixty years respectively, the other man about eighty. The woman's lesion was on the forehead, that of the younger man on the left ala of the nose. In neither of these cases do I have any fear of recurrence at any future time. They will be put upon the usual internal treatment. In the case of the older man I am decidedly of the opinion that while the disease will probably not recur at the site of that particular point operated upon, appearance may be looked for at others. He was operated on once before, and his is a curious and interesting case from other points of view. He has been under my observation now nearly a year, and I consider him to have not only a cancerous but a general diathetic degenerate condition; that he is in fact a senile degenerate. On his first appearance at the hospital his face and forehead were found to be studded with large excrescences of verrucæ latæ seborrhœicæ, that common sign of senile degeneration of skin; there was also an epithelioma on the cheek, the object of the first operation; and besides these he had two or three subcutaneous tumors, as large as horse-chestnuts, on and over the right shoulder blade and on the ridge of the shoulder itself. These lumps were all to a small extent movable under the skin, and were pronounced by all medical men who examined him as being in all probability sarcomatous tumors. They interfered with his freedom of arm motion and were painful to touch. He was put under large and increasing dosage of arsenic. Under that treatment these tumors in a few weeks completely disappeared, and have not since recurred. His movements, save for age-stiffness, are as free as they have ever been; his face has cleared up greatly, and complexion freshened. No history of syphilis, no subjective or objective symptoms were obtainable. I think it extremely likely that in this particular case other manifestations of malignant predisposition will occur; as I have stated, he is the subject of senile degeneration as to the tissues, and nothing but the results of this state can be expected.

I have had other cases of multiple sarcoma in which some of the tumors have been by competent authorities examined after excision, so that no possible doubt could exist as to their nature, in which the same treatment has been used with equally good and very much more surprising results. I will not further speak of it here, but reference will be found noted at the foot of page 746, to which publications I would refer any one interested in the subject.[1] Köbner's and Funk's writings, and perhaps experience, antedate my own in this connection with sarcoma. I do not claim originality by any means; several of the older writers have recorded experiences in connection with epitheliomatous growths with similar treatment and favorable result; and I am inclined to think still, in spite of the dictum of the doctor and others, that its usefulness will at some day in the near future be recognized. As to reasons for its inhibitory and relatively curative action I am past theorizing. I simply recognize, as I think, the fact and let it end there (there is a temptation to quote Goethe here, but I will resist). Certainly, however, arsenic has great power in some of the keratoses and affections of the epithelial strata of the skin; this is a well-recognized fact in dermatology, as it is a fact also that some skins are more recalcitrant and less affected by it than others. Another claim that it has great action also on the fibrous tissues, at least in those in which a morbid state is present, cannot, I think, well be controverted. In what peculiar way or means it furnishes its power, whether by formation or antagonism of varying toxins, etc., I have not the remotest idea; my only comprehension lies in observation of a clinical fact. The same may be said about mercurials and their action on the economy. I do not believe any one can give me absolute and unqualified instruction thereon. From Rokitansky to Koch, and later, I have seen pathology twirled like a shuttlecock, and am content to wait, but not to expect during my life a final decision on many of these moot points.

At the commencement of this explanatory paper I had not intended to make it so long, and perhaps diffuse, but I cannot now resist the inclination and opportunity of adding a few words in general advocacy of the caustic agent I employ, and place such reliance on, in other affections of the skin—to wit, "acid nitrate of mercury." In leucoplasic growths on the lips, buccal mucous membranes, etc., I use it with great advantage, as can be certified by members of the New York Dermatological Society. My method in these cases is first to protect the normal mucous membranes and mouth *in toto*, by packing with absorbent cotton, then applying the solution in full strength to the parts affected, and, when I am satisfied that sufficient escharotic action is obtained, neutralizing as usual with bicarbonate of sodium in substance and solution.

In cases of the little teleangiectases (so-called spider cancers) of the face and other parts of the body, I find that the point of a toothpick dipped into the solution, and pricked into the centre of the arborescent lesion, is, from the adhesive inflammation it causes, much more effective than, we will say, the touching with the galvano-cautery point so often employed in these cases.

One last word. In an able review of the modern varieties of treatment of lupus, by Dr. McLeod,[2] entitled "Observations on Some of the More Recent Methods of Treating Lupus Vulgaris," he mentions and extols Dr. Unna's latest mode, consisting of soaking a number of small wooden pegs in a mixture of the solutions of acid nitrate of mercury and carbolic acid, boring these into the nodules of the lupus growths, then cutting the ends off just above the niveau of skin, and allowing the rest to remain. Now, for the life of me, I cannot understand wherein the advantage lies of making a human being a sort of hedgehog, instead of curetting at once and applying the remedy more directly, which has been my ordinary method for many years, and a fairly successful one; so much so that I can hardly understand the jeremiads of many better men over their acknowledged almost total failure in the treatment of this class of cases.

I am bound as freely to admit that recurrence more often happens in them than in any of the other classes mentioned; as to the reasons for this, whether owing to the extent and greater diffusion of lesion, the almost consequent lighter curettage and application, etc., I confess that I am not altogether clear, but success certainly is very frequent.

S. SHERWELL, M.D.

33 SCHERMERHORN STREET, BROOKLYN, N. Y.

HOSPITAL SURGICAL SERVICE CONDUCTED BY A SINGLE CHIEF.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a fitting encomium of the services rendered by Dr. McBurney to the Roosevelt Hospital, in the editorial pages of your issue of April 14, 1899, attention is directed to the demonstration he has afforded of the practicability and feasibility of a large hospital surgical service being conducted by a single chief.

I would like to call attention to a similar demonstration, afforded by Dr. A. G. Gerster, at the Mount Sinai Hospital of this city, where for three years, from December 1, 1896, to December 1, 1899, he, with the aid of two adjunct surgeons (Drs. Lilienthal and Van Arsdale) conducted and directed a most active surgical service of seventy beds.

A. A. BERG, M.D.

774 MADISON AVENUE.

THE STATIC INDUCED CURRENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have examined the references kindly furnished by Dr. E. L. Squire in your issue of March 31, 1900, concerning the above subject, and find that they have not the slightest relation to it. I have carefully read the quotation from Beck's Murray, "A System of Materia Medica and Pharmacy," published in 1828, vol. ii., p. 240, and find (as appears by Dr. Squire's quotation) merely the usual classical description of the medical applications of statical electricity, with no allusion to currents of any sort. The reference therefore, however interesting, has no bearing upon the discussion in question, and I am at a loss to account for its being adduced on any reasonable basis.

Dr. Squire's second reference is to "Braithwaite's Retrospect," 1845, part xi., p. 33. The article (really on pages 29 and 30) is taken from the *Medico-Chirurgical Review*, vol. i., p. 319, published in 1845. This *Medico-Chirurgical Review* article in turn is based upon an article by MM. Longet and Ch. Matteucci, "Upon the Connection between the Direction of the Electric Current and the Muscular Contractions Excited by that Current" (translation), published in the *Comptes rendus de l'Académie des Sciences* of September 9, 1844, and upon the electrophysiological work of C. Matteucci. Turning to the above and to "Leçons sur les Phénomènes Physiques des Corps Vivants, par C. Matteucci," p. 255, published in Paris, 1847, we at last get at the true reference, which is (translated): "A current which circulates by jerks in an animal during a certain time produces tetanic convulsions; the direct current, if continued sufficiently long, produces, on the contrary, paralysis."

At this point our researches come to a sudden termination, not with an electric, but with a moral shock, for in reading over the articles referred to we find that Matteucci's investigations relate only to interrupted galvanic currents and not even remotely to statical electricity. And we find that the writer in the *Medico-Chirurgical Review* quoted does not use the term "static induced current," which in Dr. Squire's quotation is included within his quotation marks as if the original writer had so used it. It is, therefore, evident that Dr. Squire's juxtaposition of quotations, at one point referring to the common statical electrizations and at another to the common galvanic electrizations, and at no point referring to the static induced or any similar current, is more ingenious than it is ingenuous.

Journal of Cutaneous and Genito-Urinary Diseases, vol. v., January, 1887. —"Multiple Sarcomata: History of a Case Showing Modification and Amelioration of Symptoms under Large Doses of Arsenic." The American Journal of the Medical Sciences, October, 1892.—Remarks in Transactions of the American Dermatological Association, Twenty-third Annual Meeting, 1899.

[2] British Journal of Dermatology, vol. xi., 1899, p. 341.

It goes without saying that an interrupted galvanic current produces, and always did produce, tetanic contractions, but what I said, before any one else said it, was that currents were derived from electrostatical machines by setting up a spark gap, independent of the patient but in the same circuit. I have yet seen no reason, nor can I believe any impartial observer sees any, to cause me to withdraw this claim.

William J. Morton, M.D.

April 10, 1900.

Medical Items.

Bloodletting versus Leeches.—In an article on the treatment of pneumonia in the *Revista Ibero-Americana de Ciencias Médicas* for December, 1899, Dr. Rubio says that a more marked and more prolonged anæmic condition follows the loss of blood by leeches than by phlebotomy. The abstraction of thirty-two or more ounces by phlebotomy produces less pallor and causes less weakness than does the loss of eight ounces of blood sucked by leeches. This difference is especially marked in children. He explains the anæmia following the application of leeches by the presence of a blood poison in the leech in consequence of which the blood remaining in the body is vitiated. Professional leech catchers, men who wade barelegged into places where leeches breed, rapidly acquire a peculiar cachectic appearance, which is not due to the loss of blood, for they remove the animals immediately they attach themselves, before an appreciable amount of blood has been lost.

Hospital Train for South Africa.—A hospital train for South Africa is being built at Birmingham, England. The following is a description of the train given in an English weekly journal: "After several unsuccessful attempts to purchase and adapt carriages which were being built for the South African Railway, and were required for army purposes, the central British Red Cross committee voted a sum of money for the building and equipping of a complete hospital train. The borough of Windsor having contributed a sum of £6,100 ($30,500) to which Princess Christian added £650 ($3,250), the balance of a Red Cross fund which was invested in her Royal Highness's name after the Soudan campaign of 1885, and several other donations having been made, including £200 ($1,000) from the Worcester committee and one of £50 ($250) from Canada, it was only natural that the wish expressed by the Royal borough that the train should be named 'Princess Christian,' should be carried out. The train consists of seven bogie 'corridor' carriages, each about thirty-six feet in length and eight feet in width, the passage through the centre being continuous. No. 1 is divided into three compartments for linen and other stores, for two invalid officers, and for two nurses respectively. The second carriage is also divided into three compartments—namely, for two medical officers, a dining-room, and a surgery. Nos. 3, 4, 5, and 6 are each constructed to carry eighteen invalids and four hospital orderlies, It is here that the greatest difficulty was experienced. owing to the line being of narrow gauge and the space being consequently so very limited. The beds have been necessarily placed in three tiers, and any person accustomed to the lifting and moving of invalids can understand how difficult it is to place a helpless patient sideways on a bed closed on all sides but one, from a gangway two feet six inches in width, in which there is only room for one bearer at the head of the stretcher and one at the foot. This difficulty has been overcome by an arrangement of pulleys in the roof which enables each bed with a patient on it to be raised to the proper level by one man, while the hands of the two bearers are thus left free to guide and fix it in position. Each carriage is provided with a stove, a lavatory, and necessary storing lockers. No. 7 contains the kitchen and pantry, including berths for two cooks and a compartment between for the guard. There are perfect hygienic appliances for cooking, several large cisterns containing cold-water storage, two large filters, refrigerator, and in fact everything necessary for ninety-seven persons, even if they had to live on the train for two or three weeks. Many little luxuries have been added by Princess Christian and all the members of the Royal family, including the Queen, who has sent some thick, warm blankets."

The Frisch Bacilli in Nasal and Oral Mucous Membranes.—Simoni (*Centralblatt für Bakteriologie*, Nos. 18, 19, 1899) declares that he has long had doubts, after studying recent literature on the subject, whether rhinoscleroma is contagious or not, and whether the Frisch bacillus is really the specific etiological factor of this disease which it has been claimed to be. He has found in the secretions of ozæna encapsulated bacilli which could be isolated and which were identical with those seen in rhinoscleroma. He now cites an extended experience of seventy-six cases, of which fifty-eight were human beings, all suffering from nose affections, while the remaining eighteen were animals with acute and chronic catarrhal nasal conditions. From these cases and from the nasal mucus of healthy persons, the author made gelatin and agar cultures. After thorough and painstaking investigation he comes to the conclusion that the Frisch bacillus and the Friedländer pneumobacillus are merely varieties of the same species widely distributed in nature, the extremes of which may be seen in the Frisch bacillus on the one hand and the Löwenberg-Abel bacillus (Bacillus mucosus) on the other. Besides this, Simoni proves that these bacilli are found in the nasal mucous membrane at the site of minor injuries, and are almost always present in the mucous membrane of animals. He also declares that Frisch bacillus is a frequent and innocent guest of both the nasal and laryngeal cavities.

Leeches and Bedbugs as Germ-Carriers.—In his experiments, Mühling (*Centralblatt für Bakteriologie*, No. 20, 1899) used the bacillus of anthrax and proved the existence of an internal infection of anthrax in bedbugs which had fed on the blood of mice likewise affected. Furthermore, a horde of bacteria settled on bugs which had been allowed to wander over the remains of mice infected with anthrax. The infected bugs had present in their intestinal canal virulent anthrax bacilli which finally passed away unchanged in the fæces. Mühling does not state that he experimented further with the view of ascertaining whether or not any virulence remained with these bacilli voided in the fæces. The bugs, however, were not visibly affected by the bacillus anthracis, which fact the author proves by stating that he kept such a bug alive and under observation for six weeks. The bite of such an infected bedbug upon a mouse was without result. However, if, while sucking at the wound, the bug was crushed with a sterile glass rod, and rubbed therewith over the surface of the wound, thereby insuring the freeing of the intestinal contents and simultaneously of the contained anthrax bacilli, there was obtained in every single case as a result the infection of the mouse. The author believes that the bedbug only sucks blood from its victim, and that no germs can escape from it to its host in the process (?). Leeches are very similar to bedbugs in these respects. Thus, they do not succumb to anthrax. Mühling declares that he kept such an infected leech living for three months. On the other hand, however, the anthrax germs, after having been taken up by the leech, die in that animal's intestinal canal after so short a period as a single day. The author did not satisfy himself as to the reason for this. Mühling concludes that even though it should accidentally happen that the germs attached to the external surface of the leech find their way into the wound, they would be sucked up by the leech in the process of blood-transfer, and therefore that parasite could be used therapeutically without any danger of infecting its host, on both man and animal.

Osteopathy has at last invaded the metropolis. The first practitioner to make himself known here is out in a circular telling of the many things he is capable of accomplishing. It begins: "I, as an osteopathist, do not advocate the use of drugs." He appeals to the medical profession to send him cases. The strange part of it is that some of its members will. However, he would get them anyway.

Old Specula.—The *Bulletin d'Oculistique* relates a story answering the query, "What becomes of the old speculum?" A physician happening to enter the kitchen in a country hotel saw a brightly polished bivalve hanging among the cooking utensils, and upon inquiry learned that it was used by the cook for moulding sausages. The proprietor had bought it at an auction of second-hand household effects.

Alcoholism in the United States Army.—During the calendar year 1898, 707 cases of alcoholism were reported as having been under medical treatment in the regular army. Ten of the cases had a fatal ending. These cases gave for the year an admission rate of 15.16 per thousand of strength. This rate compares favorably with the rate in 1897, 27.86, and the mean annual rate of the previous decade, 36.90. These rates do not represent the amount of intemperance existing in the army or in any of its parts, but as they are all calculated from similar data, to wit, the number of cases in which medical assistance was invoked to avert danger, they are useful for purposes of comparison. The rates of admission in 1898 were highest during the first three months of the year, when the troops were in garrison under conditions of peace. They were lowest during the period of active field service, May to August inclusive. In Cuba drunkenness was measured by an annual admission rate of only 0.52 per thousand of strength, while in Puerto Rico a rate of 18.65 was associated with 2.07 deaths in every thousand men. In the Philippines the facility with which alcoholic liquors could be procured resulted in a rate of 21.70, but this rate was somewhat exceeded in the artillery arm of the service in garrison in the United States. During the past year as in previous years the colored troops had a lower rate, 4.81, than the white troops, 15.96.—*Report of the Surgeon-General of the United States Army.*

Good Stomach, one of the Sioux Indians now exhibiting in Paris, will have to change his name. French brandy proved too strong for his gastric digestion, and he was arrested the other day for going on the warpath in the French capital.

Gonorrhœa of the Stomach.—Dr. J. H. Oyster, of Paola, Kan., writes to the *Medical World* for the best treatment in gonorrhœa of the stomach. He has a patient so affected for five years, due to extension from the mouth.

"La Fécondité."—The *Gazette Médicale de Paris* takes exception to the statements made by Monsieur Zola in his recent novel relative to the part played by reputable surgeons in the depopulation of France. It is admitted that many women have their generative organs unnecessarily mutilated, and that many do so by choice, so as not to bear children; but the *Gazette* claims that all this criminal work is done by unscrupulous members of the profession, who are generally known and also generally detested.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 20, 1900:

PERFORATING DUODENAL ULCERS.[1]

BY ROBERT F. WEIR, M.D.,

NEW YORK,

PRESIDENT OF THE AMERICAN SURGICAL ASSOCIATION; SURGEON TO THE ROOSEVELT HOSPITAL, ETC.

THE interest that has been lately directed toward the surgical treatment of gastric perforations has also been turned to the operative relief of the allied round or peptic ulcer of the duodenum. This affection is much rarer than the ulcer of the stomach, is much more difficult to diagnosticate properly, and is more apt to be confounded with other more distant surgical lesions, such as appendicitis, etc.

Site.—Its site is in the upper part of the duodenum, and according to Morot[2] and Vonwyl[3] it is always situated within one and one-half inches of the plyorus; but Schwartz[4] gives one case in which the perforation existed on a level with or a little below the ampulla of Vater, and thus allowed a free escape of bile into the peritoneal cavity. The figures given by recent authorities show that in the two hundred and sixty-two collected cases of Collin,[5] the perforation occurred two hundred and forty-two times within two inches of the pylorus, in the descending portion fourteen times, in front of the aorta three times, and in the ascending portion three times. Or, expressing the same a little differently, one hundred and sixty-two of the two hundred and sixty-two cases were situated at 2–4 mm. from the pylorus; seventy-five close to it; four encroached on the pylorus itself, and two extended through the pylorus to the duodenum and to the stomach. Perry and Shaw[6] found, in one hundred and forty-one cases of duodenal ulcer, one hundred and twenty-three in the first part of the duodenum, sixteen in the second part, and only two in the third part.

Number.—These ulcerations are usually single. Collin says that one ulcer was found in eighty per cent. of his cases; two ulcers in eleven per cent.; and three or four ulcers in four per cent. Morot in twenty-two cases found eighteen had a single ulcer; two, two ulcers; one, three ulcers, and one four ulcers.

Location.—These perforations are encountered most frequently on the anterior wall. Oppenheimer[7] in fifteen cases noted that the perforation had taken place in the anterior wall eleven times, three times posteriorly, and once superiorly. Of the one hundred and nineteen cases of Collin in which the first portion of the duodenum was perforated, in sixty-eight it occurred on the anterior wall of the bowel, in thirty-nine the posterior wall, in ten the superior, and in one the inferior portion. In eight ulcers perforating in the second portion of the bowel, five occurred in the internal wall, two in the posterior, and one in the external wall; and in the ulcers presenting in the third part of the duodenum, four in number, in three the anterior and superior walls were involved, and in one the posterior wall. This is of considerable surgical importance. The anterior perforations are, for obvious anatomical reasons, less likely to be closed off by adhesions, and hence a free and rapid involvement of the peritoneal cavity takes place in the openings here situated. Reckmann[1] states that half the cases of duodenal ulcer result fatally from perforation into the peritoneal cavity.

Frequency of Perforation.—Perforation is said to take place one hundred and eighty one times in Collin's two hundred and sixty-two cases, or in sixty-nine per cent.; Chvostek, however, places the frequency of perforation at about forty-two per cent. of the cases. In these two hundred and sixty-two cases there was a generally diffused and fatal peritonitis, one hundred and twenty-five times. But occasionally in anterior openings, but more commonly with the perforations existing elsewhere, adhesions or ulcerations with abscess and hemorrhage of the duodenal wall or adjacent organs have been encountered. Examples of such complicating lesions are subphrenic abscess, which follows more commonly a perforation in the superior wall of the horizontal portion of the duodenum (according to Oppenheimer). Liver and pancreatic adhesions are at times met with (Oppenheimer gives six cases and Collin thirty-eight cases of such adhesions). Perforations into the gall bladder have been reported, but more important and dangerous are the ulcerations into the aorta (Stich,[2] two cases), or the vena porta (Rayer and Habershon, two cases), or the superior mesenteric vein (Warfinger), or the hepatic artery (Vonwyl). The ulceration has been also known to invade the adjacent colon (Murchison and Saunderson, two cases).

Sex.—Duodenal perforations are more common in men than in women; about seventy-nine per cent., according to Collin, are in males. From the tables of Morot, Kraus, Lebert, and Chvostek I have gathered one hundred and seventy-six cases of duodenal ulcers, and of these one hundred and forty-four were in men and thirty in women.

Cause.—This has been explained by Boas[3] to be due to the rougher food, and, in men, to their addiction to alcohol and tobacco, which intensify the acidity of the gastric juice, and thus acts unduly on the glandular mucous membrane of the duodenum, which is not protected until the alkaline bile and pancreatic fluid is poured into the intestine at the opening of Vater. Koch and Ewald, by giving to animals hydrochloric acid, 5 : 1,000, caused duodenal ulcers to appear. Pyloric spasm, Talma states, produces necrosis and anæmia of the membrane there. On the other hand, alcoholics are not found to be prone to duodenal ulcer, and though the spasms and lesions of gastric hyperacidity, which are now accepted as a causative of stomach ulcer, will doubtless apply in many instances to the development of a similar duodenal damage, there are other causes for duodenal ulceration to be mentioned beside the foregoing.

Burns.—The principal and best known, though now somewhat disputed factor in their etiology is the influence of external burns. Holmes,[1] for instance, states that in one hundred and twenty-five cases of burns, sixteen cases of duodenal ulcer were found; Perry and Shaw in one hundred and forty-nine cases of burns met with duodenal ulcers five times; and in Collin's two hundred and ninety-seven cases of duodenal ulcer he states that burns produced the ulceration in thirty-eight instances. According to Holmes, the duodenal ulcerations after burns present themselves from the seventh to the fourteenth day, but Ponfick found in one instance a duodenal ulcer within eighteen hours after the reception of the burn. Curling also had a case in which symptoms of duodenal ulcer were recognized one day after the burn, and the autopsy confirmed the diagnosis.

The explanation most accepted at the present day is that this complication of a burn is due to septic infarctions such as may be developed in frost-bite, of which Billroth and Adams each cites a case, or in erysipelas, eight instances, or in tuberculosis (Latham). In the cases in which trichinosis (Ebstein), or heart or kidney disease, or cirrhosis, or hepatic or other carcinoma (Latham) exists, it is not quite so easy to trace the connection, though embolism even here has largely to deal with the question. The recognized explanation offered by Hunter[2] and often quoted, seems inadequate to elucidate the relation between a cutaneous burn and a duodenal ulcer. This observer proved that in animals treated by injections of toluylendiamin the bile was so changed that when discharged into the duodenum ulcerations rapidly developed. His idea, therefore, was naturally that the alteration of the cutaneous covering so altered the bile as to beget the complicating duodenal ulcerations. Unfortunately duodenal ulcers are so rarely met with on a level with or below the bile discharged into the bowel, that this at once disposes of the need of calling on the liver and pancreas as accomplices in their production. That septic infarction is the most probable cause of duodenal difficulties after burns may also be fairly inferred by the later collection of Lockwood, who, in one hundred and thirty-eight cases of burns treated with more or less approach to an antiseptic idea, noted the complication of duodenal ulcer in but one instance. A cancerous ulceration is almost unknown; but four cases (Eichert, Ewald, Schrotter, and McKenzie) have been recorded.

Frequency.—A duodenal ulcer is, according to statistics, a rare lesion. Collin, whom one is compelled to quote by the worth of his collected cases, in a range of ten years could find only twenty-six cases. Houze[3] in three additional years could add only three more cases, though Darras[4] more than one year later found five others. Since attention has been given to the subject, and particularly to the surgical aspect of it, by the present writer in 1896, when nine cases were reported as having undergone surgical treatment, there have been reported fifty-one operations for this disease.

The relative frequency as a cause of death deduced from autopsies is as follows:

Willigt	1,600	sections with	74	gastric ulcers and	2	duodenal.
Starke.....	384	" "	36	" " "	3	"
Crunfeld...	1,150	" "	124	" " "	4	"
Steine.....	3,085	" "	89	" " "	12	"
Vonwyl....	12,806	" "	98	" " "	3	"
Latham....	8,192	sections with	..	gastric ulcers and	12	duodenal.
Perry and Shaw....	17,652	" "	..	" " "	70	"
N. Y. Hospital (unpublished)	1,000	" "	..	" " "	2	"
	45,869		421		108	

or about 0.2 per cent. in frequency.

Kinnicutt,[1] however, in thirty thousand autopsies, which probably included many embraced in the above table, has given a rather higher percentage of frequency, placing it at 0.4 per cent. Though the proportion is a small one, stress must be laid on the fact that from forty per cent. to seventy per cent. of these ulcers perforate, with an almost invariably fatal result. The relative proportion of gastric to duodenal ulcers is 12 to 1 (Burwinkel).

Age.—It is encountered at all ages. Chvostek in eighty-seven autopsies on children under ten years of age, found five duodenal ulcers, of which one was seen in a seven-weeks-old child, another in a child four days old, and a third in a babe of three hours. Collin's table is the most complete in this respect, and it is here presented. In two hundred and ninety-seven cases of duodenal ulcers they were met with:

Under 10 years of age	42	times.
Between 10 and 20	24	"
" 20 " 30	43	"
" 30 " 40	52	"
" 40 " 50	46	"
" 50 " 60	41	"
" 60 " 80	28	"
" 81 " 95	3	"

Progress.—It has already been strongly stated that nearly all perforations of the duodenum will prove fatal from a generalized peritonitis unless surgical intervention should relieve the patient. What this consists of, what are its results and its difficulties, will be considered a little later. At present one must take account of the somewhat encouraging fact that all duodenal ulcers do not go on to this severe complication of perforation. At seventy autopsies, Perry and Shaw found decided evidences of repair in nearly fifty per cent. of the cases, and Collin also recorded thirty-nine instances of cicatrized ulcerations. These cured ulcers may prove innocuous, but they can, as in the stomach, narrow to a dangerous degree the lumen of the intestine and even encroach upon the bile opening, or make such traction upon it as to bring about gastric and hepatic dilatations. Some of the most brilliant surgical triumphs have been obtained in relieving such obstructions, of which examples may be subsequently found in this article.

Symptoms.—The symptoms of a non-perforated duodenal ulcer are, as shown by Schwartz, frequently very slight. In twenty out of twenty-five instances of perforation the patients were in apparent good health, or so slightly indisposed that they had not consulted a physician. In only five cases were there previous stomach symptoms. Of these one patient was thought to have dyspepsia, and two to have a gastric ulcer. In my own collection of fifty-one cases treated by operation, gastric symptoms previously existed in twenty-five out of thirty-four cases.

The usual signs may be given as follows:

1. The pain, when characteristic, occurs several hours after eating, and may be slight or severe, and presents itself just below the gall bladder, and may reach to the median line or to a level with the navel. Many times the pain is absent. Reckmann in eighty cases found sixteen in which little or no pain existed. Pressure particularly over the region to the right of the twelfth thoracic vertebra occasionally elicits pain.

[4] "De la perforation de l'ulcère simple du duodenum." Thèse de Paris, 1896.

[1] Jacobi: Festschrift, 1900.

Swallowing of a sour lemonade or a strong alcoholic drink may arrest the pain by bringing about a pyloric contraction, but Pagenstecher[1] denies the value of this test.

Vomiting is present in about seventeen per cent. of the cases, but it is of a reflex character. It is of diagnostic importance if, like the pain, it shows itself from an hour or so up to several hours after a meal, and the matters rejected are broken-down food often mixed with bile and blood.

The right shoulder pains are noted by Schwartz as occasionally to be recognized. According to Vonwyl and Bucquoy, the pains are often slight from the comparative immobility of the duodenum, and vary from queer indescribable sensations to severe radiations of distress. Vomiting, when it occurs, relieves the pain.

Jaundice, if present, which is rare, may be due to simple duodenal tumefaction or to cicatricial contraction on the papilla.

Hemorrhage is to be expected in about one-third of the cases of non-perforating ulcers. Probably it is even more frequent than this, as Oppenheimer found blood in the stools of one-half of his thirty-four cases, and Krauss says it occurs even more frequently than in this ratio. This bleeding can be severe and show itself by mouth as well as per rectum. It can speedily prove fatal, as larger vessels are opened than by a gastric ulcer. Usually the blood is discharged from the bowels in a tarry condition, which bespeaks a high origin of the hemorrhage and an exposure of some duration to the action of intestinal secretions. This is spoken of as melæna. Its color may be, however, a bright hue, and recently, with Dr. Peabody, the question of the presence of a duodenal ulcer in a patient with intestinal hemorrhage and right-sided epigastric pain and distress some time after eating, was negatively decided because the blood discharged per anum was of a bright red color and unclotted. As the patient, moreover, had hemorrhoids the possibility of this origin led to the confusion in diagnosis. This escape of fresh unchanged blood from the bowels is recognized by Vonwyl, and some emphasis should hereafter be placed on this possibility. The profusion of the hemorrhage may be much beyond that encountered in gastric ulcer, for larger vessels may be involved. Collin gives twelve instances in which the blood came from the pancreo-duodenal artery; three times the gastro-epiploica dextra was opened into; twice the pancreatic artery; once the hepatic; twice the aorta; twice the vena porta; and once the superior mesenteric vein. Pagenstecher states that the ulcers on the posterior wall are more apt to bring about hemorrhage than the anterior ones, as the vessels are more abundant and larger there. Burwinkel[2] says that excepting in vicarious menstruation and typhoid fever intestinal hemorrhage in large amounts is very rare and should excite suspicion of gastric or duodenal ulcers. This writer, in spite of all that has been advanced by Nothnagel, Ewald, Lemke, and latest of all Kinnicutt,[3] that in the great majority of cases a differential diagnosis from gastric ulcer is impossible, claims that by a careful study of the symptoms he has been able to diagnose five cases of duodenal ulcers in the last few years.

Diagnosis.—The following contrasting symptoms have been grouped by Vonwyl as an aid to this end:

Gastric ulcer: (1) More frequent in women, twenty-fifth to fiftieth year. (2) Pain promptly after eating. (3) Relieved by vomiting. (4) Frequent biliary, mucous, and food vomiting. (5) Marked dyspeptic symptoms. (6) Frequent bloody vomiting. (7) More seldom bloody stools.

Duodenal ulcer: (1) Occurs most frequently in males. (2) Pain in right hypochondrium or to right of parasternal line. (3) Comes on two to four hours after meals. (4) No relief by vomiting; latter not frequent. (5) Bloody stools (melæna or bright blood), more common than bloody vomiting. (6) If jaundice is present, this would contribute to the diagnosis.

That medical and surgical education in this line is progressing has also been brought out in the cases of operations which form the basis of this paper. Here it will be seen that, notwithstanding that the greater part of them have been treated as of appendical or other origin, surgeons, awake to the possibilities of the case, are making shrewder diagnoses, and the reproach which was good up to a year ago, that no operation for a previously recognized perforated duodenal ulcer had yet been performed, no longer holds good. It may be expected that as the detection and treatment of a perforated gastric ulcer have so rapidly and so satisfactorily progressed, from 1892 when the writer was able to add to his first operation of this kind but four other instances, while now over one hundred cases each year are operated on with a mortality that has fallen (if operated on within twelve hours) from thirty-nine per cent. to seventeen per cent. (Keen),[1] a similar improvement will take place in the recognition and the proper treatment of duodenal ulcers.

The picture is a far different one when the duodenal ulcer perforates, and particularly if anteriorly, which is the most common site of this complication. Here there is usually no withholding adhesion, and a rapid invasion of the peritoneum is probable.[2] If the stomach is yet filled, the extravasation may take an anatomical course somewhat in the order spoken of by Pagenstecher, and which is in accord with my own analogous clinical experience in three perforations of the gall bladder. Fluids escaping from the duodenum or gall passages flow at first between the liver and the colon, and thence along the ascending colon, sometimes to the outside of the bowel and sometimes between the omentum and the parietal peritoneum, toward the iliac fossa; from this point they may pass over to the sigmoid flexure or into the pelvis. Given, therefore, such a free course, and with a plentiful pouring out of an acid fermenting food and gas through a direct, though small (2 to 8 mm.) opening, the symptoms presented would naturally be severe.

Great pain is usually felt at the epigastrium or to the right of this region, as was noted twenty-six times in forty-seven of my cases. It has a few times been observed at the umbilicus and in the left side, but in twenty-three others of the forty-seven instances it was simply recorded as abdominal pain. Vomiting often follows the attack of pain. It occurred in twenty-eight out of thirty-four instances. Shock is not often met with, but may be severe and fatal. Peritoneal symptoms rapidly develop with a tendency in some cases to be localized in the upper part of the abdominal cavity and in the right side; when these signs show themselves mostly to the right and at or below the level of the umbilicus, an appendicitis is necessarily simulated. When the liver dulness has been dissipated up nearly to the mammary line, air extravasation may be suspected, and when accepted as present it will aid in concentrating the diagnosis. This symptom of liver resonance, unless marked, is so often found to be due to a distended colon that it should not be much relied on.

[2] "Das peptische Duodenalgeschwür." Deutsche medicin. Wochenschrift, December 20, 1898.

[3] *Loc. cit.*

[1] Keen. Brit. Med. Jour., June 11, 1898.—Mayo. "Surgery of the Stomach." Lancet, March 19, 1900.

[2] It should also be remembered that generally the duodenum in its first part is free and covered by peritoneum, so that extravasation is likewise possible through a posterior perforation in this region. It is, however, in this case more likely to enter the omental bursa (lesser omental cavity) or invade the retroperitoneal tissues.

In considering the diagnosis of a perforated duodenal ulcer as just given, I cannot but feel that more weight and attention should be given, first, to the previous history, which shows, contrary to the opinions of many anterior observers, that in the fifty-one collected cases of operations for the relief of such conditions, there was a history of gastric or dyspeptic symptoms given in twenty-five out of thirty-four instances in which this point was noted; secondly and also important is the fact alluded to on a previous page, that the initial or early pain was developed in twenty-six instances out of forty-seven in the epigastrium; and in the right hypochondrium thirteen times. The third factor of value in the diagnosis as well as the treatment of the symptoms of perforation peritonitis, whether from stomach, duodenum, gall-bladder, appendix, or any other part of the intestinal tract, is the prompt resort to an exploratory incision. This need of an early solution of the site of a perforation has been already shown in the cases of a gastric perforation, in an article[1] embracing seventy-eight cases operated upon for this trouble. The mortality in these cases clearly depended on whether the patient underwent surgical intervention within twenty-four hours from the inception (*i.e.*, the pain) of the perforation. This is yet more strongly marked in the latest collection of this class of troubles by Mayo,[2] who states that in four hundred and twenty-nine cases of gastric perforations those operated on in the first twenty-four hours were eighty-two, in which forty-seven patients recovered, and thirty-five died (forty-two per cent.); and that in operations done after that period over seventy per cent. of the patients died. In duodenal perforations the same outcome is observable. In the fifty-one collected cases herewith presented of duodenal perforations, there were twenty-five cases in which the lesion was recognized and closed at the operation; of these thirteen underwent operation after thirty hours' delay, and all resulted fatally;[3] twelve other patients were operated on within that time, and eight survived, giving thus only 33⅓ per cent. of mortality. Only, I say, and with much satisfaction, since it marks an improvement on the statistics of Pagenstecher, which gave a mortality of sixty per cent. in the found and sewn-up duodenal ulcers collected by him. Of equal value as illustrating the increasing alertness of the surgeon is the fact that prior to 1895, in the twenty-eight cases reported up to that time in which laparotomy was done for duodenal perforation, in fifteen, or seventy-five per cent., the ulcer was not found; in five, or twenty-five per cent., it was found and sutured. In only two cases, or ten per cent., was the possibility of a duodenal perforation considered. Contrast this with the thirty-one cases operated on since 1895, when the analogous surgery of gastric ulcer began to be developed. Of these thirty-one cases the perforation was not found in only eleven per cent. It was found and sutured in twenty cases, or sixty-five per cent. Its presence was considered in diagnosis in eleven cases, or thirty-five per cent.

Another indication showing the advance in our surgical art since attention has been directed to this lesion is the circumstance that it has been possible in thirteen of the more recent instances either to arrive at a correct pre-operative diagnosis, or to make the alternative diagnosis varying between a duodenal and a gastric perforation. The difficulties that have been experienced are succinctly shown in the following statement:

Diagnosis wrong; ulcer not found:

Diagnosis as acute peritonitis	8 times.
" " appendicitis	15 "
" " intestinal obstruction or appendicitis	1 time.
" " strangulated hernia	1 "
" " hydronephrosis	1 "
	26

Diagnosis wrong; ulcer found:

Diagnosis as acute peritonitis	5 times.
" " intestinal obstruction	4 "
" " appendicitis	3 "
	12

Diagnosis right or approximately so; ulcer found:

Diagnosis as duodenal ulcer	5 times.
" " gastric or duodenal ulcer	6 "
" " appendicitis or duodenal ulcer	2 "
	13

Treatment.—For the treatment of a duodenal ulcer the medical means applicable to the management of a gastric ulcer also hold good. It is but seldom that surgical aid is called for before perforation has occurred, but the cases reported by Codevilla[1] are of much surgical interest and instruction. This surgeon, for the relief of symptoms that fairly well pointed to an intractable duodenal ulceration, resorted to a gastroenterostomy in two cases, with a cure as the result of his intervention.[2] In some cases of perforation the shock and progress of the infection are so rapid as to bring about death in a few hours. Stevens[3] quotes a case in which a fatal issue occurred within twenty-one hours after the first symptom (sudden pain) had shown itself.

When the diagnosis has happily been narrowed down to a perforation of either the stomach, duodenum, or gall bladder, the incision to be advised is in or along the edge of the rectus muscle four to six inches in length and starting rather low down on the abdominal wall, so as not to reach much above the liver edge but to extend far enough downward to get easily below the transverse colon, which might be necessary. Supplementing this incision in its upper third another transverse one in the skin to the left or toward the median line is advisable. This will permit the cross-division of the fascia covering the right rectus muscle, which latter is in turn to be pulled to the left, when its posterior sheath with the peritoneum is also to be divided. This gives a satisfactory and largely increased exposure of the parts beneath, and the subsequent suture of the upper and lower sheath of the rectus with the full replacement of the muscle adequately restores the integrity of the abdominal wall. This incision I have made many times in operations on the gall bladder, and similarly in numerous instances of suppurating appendicitis when increased space is necessary.[4]

If gas or food material escapes when the abdomen is opened, the surgeon's action is rendered more certain, and by a rapid and thorough inspection, after wiping away any obscuring fluid, of the gall bladder, duodenum, and the anterior walls of the stomach, the perforation can be disclosed. If nothing is visible in these regions, the examination of the posterior gastric wall can be accomplished by either tearing through the gastro-colic omentum, or by turning up the omentum and large bowel and entering the lesser omental cavity through the mesentery as in posterior gastro-enterostomy. From the lower end of this wound, which is large enough to admit the hand, the appendical region can be explored in many instances if it should be necessary, though probably if this should be involved a separate incision might be more suitable. If a duodenal perforation exists, it will generally be found on the anterior wall of the duodenum as a small round opening, rarely beyond one-quarter of an inch in diameter, with comparatively thin edges and rarely adherent to any adjacent intestine. Gas or fluids have frequently been seen passing from the opening, and occasionally bile, which latter may also stain the peritoneal extravasation. Mayo has suggested that an acid reaction of the peritoneal effusion might help in suggesting, prior to its discovery, a gastric or duodenal opening, but as the inflammatory effusion rapidly neutralizes the stomach acidity, this will seldom be of help.

---

[2] Mayo: *Loc. cit.*

[3] One case (No. 31), however, recovered after a delay of two hundred and sixteen hours, but here the perforation had formed a chronic abscess and sinus.

[1] Codevilla: See Pagenstecher, *loc. cit.*

[2] Berg and Roux also each report a case in which for a duodenal ulcer with adhesions or pyloric stenosis a similar operation was done with success.

[3] Glasgow Medical Journal, vol. li., p. 87, 1897.

[4] Weir. Medical News, February 17, 1900. "On an Improved Method of Operating for Acute Suppurating Appendicitis," Medical News, March, 1899.

Since several of the collected cases have shown in the abdominal extravasation the presence of recognizable medicines, such as castor oil, etc., given erroneously to move the bowels, it may be considered worth while to utilize this fact, and to give, prior to the operation, a certain amount of methyl blue or other innocuous colored solution to aid in the detection of the opening. When found, the perforation should be closed by a double or triple row of interrupted silk sutures. No attempt should be made, in my judgment, to excise the ulcer before suturing. This takes too much time, and the results in the collected operations show that in seven out of nine of the successful cases suturing alone was relied upon. In one only were excision and suturing employed, and in one other case the ulcer was closed over by suturing over it the duodenum, colon, and stomach. This experience is confirmed in the large number of gastric perforations that have been treated up to date.

The suggestions given by Pagenstecher in the conduction of this operation are worthy of remembrance. They are, that the fundus of the gall bladder, when distended, lies in front of the duodenum. By raising up the transverse colon, which rests somewhat in front of and below the horizontal part of the duodenum, and by drawing it forward, this portion of the intestine is immediately revealed. Crowding the stomach and pylorus to the left and a little downward, with lifting up the liver and pushing the colon down, a good view of the locality of a perforation is obtained.

The closure of the perforated intestine, however, leaves much of the battle for life unfinished. The proper and systematic cleansing of the peritoneum is of the utmost importance. If the extravasation is limited, careful wiping out of the affected portion of the peritoneal cavity, with especial attention to the retro-gastric and supra-hepatic spaces and to the splenic and renal region, with ample gauze drainage, will in most cases suffice better than the large warm irrigations of sterilized salt solutions, which are, I think, more suitable in extensive or general peritoneal inflammations.

For those who favor multiple incisions and large irrigations the specific directions of Lennander[1] are of value. He considers, in suitable cases and in patients of sufficient vitality, that irrigation with water at 40° C. (104° F.) through several incisions, is the best method of cleansing the peritoneal cavity. One must go carefully and methodically about the solar plexus and the diaphragm; methodically loosening adhesions, irrigating, and then wiping clean with wrung-out gauze. He begins with the upper surface of the liver, particularly on both sides of the suspensory ligament; then passes between the liver and stomach to the triangular ligament, then around the cardiac portion; then between the stomach and spleen, then under the diaphragm to the left kidney, and along the spleen to the phreno-colic ligament. The division of the triangular ligament with a thermocautery has been suggested, so that one might sweep around the left lobe on both sides. He then cleans between the right kidney and the liver, kidney and colon, colon and liver; next the lumbar regions and both iliac fossæ; then both sides of the mesentery of the small intestine, and last the pelvis, which is often infected at the beginning of the trouble. A great quantity of hot fluid is of undoubted benefit in the pelvis.

Drains and tampons are intended to remove accumulating fluids as well as to shut off infected areas. Tubes surrounded by gauze are the best drains. He places sterile gauze on both sides of the suspensory ligament of the liver and between the liver and diaphragm. Drains should be placed in both lumbar regions, the left passing alongside of (better through) the phreno-colic ligament external to the spleen to the middle of the diaphragm. The right one passes to the duodenum. The pelvis of men is drained above the symphysis pubis, that of women through the vagina.

My own experience in the surgical treatment of duodenal perforation is confined to one case, which is briefly as follows:

Perforation of Duodenal Ulcer; Laparotomy; Suture; Death.—A man, aged thirty years, who had previously symptoms, confusedly detailed, of gastric disturbance but not of hæmatemesis, for several months, was seized four days previously with severe epigastric pain, chill, fever, repeated vomiting, and great prostration. No blood was expectorated or dejected. His abdomen rapidly swelled and became generally tender and painful. On his entrance into the New York Hospital, April 30, 1899, nothing could be made out by palpation save that the liver dulness was nearly obliterated. The abdomen was very tympanitic, and no special point of tenderness or dulness was observed. He also had a double hernia. On the right side there was a protrusion of intestine beyond the external ring. The pulse was 140; temperature, 104° F. The diagnosis of a general peritonitis from a gastric or duodenal perforating ulcer was made. A large median incision was made with the umbilicus in the centre for general exploration. The fingers showed nothing at the rings or at the cæcum, and then on carrying the examination upward a minute, sharply defined perforation, one-quarter of an inch in diameter, was found on the anterior wall of the duodenum near the pylorus, out of which was oozing some brandy and water given just before chloroformization. This was sutured with a double row of Lembert sutures, and the peritoneal cavity systematically and carefully washed out with sterile salt solution. He was returned to the ward in bad condition. Salt transfusion, 75 oz., etc., was made, but the patient succumbed shortly after the operation. The autopsy showed the perforation to be in the duodenum just below the pyloric termination and in its superior anterior wall. Within the bowel was a deep ulcer at the bottom of which had occurred the perforation.

Later Effects of Duodenal Ulcer and Operation for Same.—There yet remain a few words to be said about the late consequences of a healed duodenal ulcer. The resulting cicatricial contraction may bring about stricture of the duodenum and dilatation of the stomach, and may by traction or primary ulceration damage the bile entrance to the intestine. Several interesting surgical cases have been reported in which relief has been afforded by such circumstances. Pagenstecher quotes a case by Lange[1] in which a gastro-enterostomy was successfully resorted to for contraction of the duodenum to the hardness and size of the finger, 3 cm. from the pylorus, with dilatation above of the duodenum and stomach.

---

[1] Pagenstecher *Op. cit.*

Codevilla[2] details a more acute case with ulcer and stenosis of the duodenum and dilatation of the stomach. The duodenum was found at the operation markedly stenosed as in Lange's case, and a gastro-enterostomy was performed with a successful and permanently good result.

Carle[3] had a similar case in the front part of the duodenum, but the gastro-enterostomy resorted to ended fatally. He also reported another instance in which great emaciation and stomach dilatation demanded surgical interference. The first and second parts of the duodenum were found strongly contracted but with atrophic thin walls. Gastro-enterostomy was employed with success; death occurred one year later from lung tuberculosis.

Rewidzow[4] also cites a case which is doubtfully placed among these, as the locality of the stenosis following bloody vomiting and gastric disorder for twenty years was shown at the operation to be below the bile papilla, where a stenosis existed. For this a gastro-enterostomy was successfully resorted to.

Operations for Duodenal Perforations.—The following list embraces all the reported cases of perforation of the duodenum that have undergone operation up to April, 1900, and which have been carefully investigated and epitomized by Dr. E. M. Foote, to whom I am much indebted for this and other help in the preparation of this article.

No. 1. Male, aged thirty-five. A heavy drinker; no history of indigestion. For a week or so loss of appetite and indefinite epigastric pain, then sudden acute pain while at work, followed by vomiting. Two days later brought to hospital in collapse. Abdomen distended, dulness in right flank; pulse rapid and feeble; temperature, 98.8° F. Laparotomy at end of two days. Acute peritonitis, cause not discovered. Death in a few hours. Autopsy showed perforation of anterior wall of duodenum close to pylorus.[5]

No. 2. Male, aged thirty-one. Acute attack like intestinal obstruction. Diagnosis, appendicitis and general peritonitis. Operation third day. Appendix normal, general peritonitis, perforation not found. Death in a few hours.[6]

No. 3. Male, aged twenty-nine. History of abdominal colic. While in usual good health he was seized at 5 P.M. with sudden pain, followed by bilious vomiting. Some lumps of fæces and gas passed that evening, but absolute constipation followed. Next day a purgative only increased the vomiting and pain. He entered hospital on the third day, with fecaloid vomiting. On the fourth day great distention, tenderness, and pain at its maximum in right hypochondrium; pulse, 120, small, dulness in both flanks. Diagnosis, perforative peritonitis. Operation in about ninety hours; general peritonitis. The hand, thrust under the liver, broke into a cavity containing two quarts of serous liquid. The intestine was searched in vain for mechanical obstruction, and on account of weakness of the patient the operation was terminated. Death same evening. Autopsy showed a perforation "near the end of the second portion of the duodenum, externally."[7]

No. 4. Male, aged twenty-eight years, always well. While drinking tea, he had a violent pain in the left side of the abdomen. Next day, a tumor to the right of umbilicus, sour vomit, later becoming fecal; tympanites; constipation, no blood. Third day, temperature normal, pulse about 130. Operation in eighty hours (about). Incision to left of umbilicus gave vent to gas and pus, intestine sound, greatly distended; incision of intestine; suture of collapse; drainage. Death in seven hours. Autopsy showed perforation in anterior wall of duodenum; purulent peritonitis.[1]

No. 5. Male, aged forty-one years, of good previous health except slight indigestion. One year before perforation, had an attack of abdominal pain with constipation. While at work he was seized with violent pain; gastric vomiting, later becoming fecal; no blood; absolute constipation. In tympanitic stage when first seen by reporter. Respiration, thoracic; pulse, 120; temperature, 99.2° F. Diagnosis, septic peritonitis. Operation, May, 1891. Usual incision; cavity searched, no cause for suppurative peritonitis found, irrigated, drained. Death in ten hours. Autopsy showed perforation in posterior wall of duodenum, one inch below pylorus, freely communicating into peritoneal cavity when intestines were lifted.[2]

No. 6. Female, aged twenty, servant. Of constipated habit, otherwise health good. Bowels moved by salts two days before the attack. A sudden attack of pain occurred in the right hypochondrium, passing then to left side, and afterward becoming general. Vomiting of sour fluid began twelve hours after the attack of pain, and continued. There was tympanites without loss of hepatic dulness. Diagnosis of general peritonitis, cause unknown. Operation in twenty-four hours. A median incision below the umbilicus allowed the escape of inoffensive fluid. A second incision above the umbilicus disclosed the perforation one-quarter of an inch in diameter, in the posterior aspect of the duodenum, close to the pylorus. Milk was escaping through it. The ulcer was excised and sutured, the abdomen flushed. Death in six hours. General peritonitis.[3]

No. 7. Male, aged twenty-one, always in good health. Sudden pain in the lower abdomen, followed by vomiting and collapse. After eighteen hours laparotomy gave exit to much brownish, acid, non-feculent fluid. There was adhesive peritonitis. The cause of peritonitis was not found. Death in a few hours. Autopsy showed a perforation in the anterior wall of the duodenum, about five inches from the pylorus, and about five inches in diameter; a second non-perforating ulcer of the posterior duodenal wall.[4]

No. 8. Male, aged fifty-six. Brought to the hospital in a condition of tympanites, and having a right inguinal hernia. Laparotomy was done. The hernia was explored and found to be in good condition, and the incision was prolonged upward seven inches, giving vent to purulent and fecal fluid. No cause for the peritonitis was found about the cæcum or elsewhere. Death in a few hours. On the anterior surface of the duodenum, 0.5 inch from the pylorus, was a perforated ulcer, 0.5 x 0.7 inch. It could easily have been sutured.[5]

No. 9. Male, aged twenty-eight. Of good health until two months before perforation; he did not feel quite himself, but there were no localized symptoms. While ascending an omnibus, he felt a sudden pain in the abdomen; nausea and vomiting after an emetic had been given; constipation for four days, then a little fecal matter and flatus, after an enema. On the seventh day entered hospital; abdomen distended; general tenderness; respiration, 28, thoracic; pulse, 104; temperature, 99.8° F. Questioned with reference to duodenal ulcer, could not localize first pain; never any blood by mouth or in stools; only slight history of indigestion. No evidence of trouble in upper part of abdomen. Diagnosis, septic peritonitis with pus in pelvis. Operation in one hundred and fifty hours (about); subumbilical incision; two pints of pus were taken from pelvis; appendix, cæcum, and small intestine sound; higher search was abandoned as there was less peritonitis in that direction; irrigation, drainage, suture. Death in fifty-four hours. Autopsy showed septic peritonitis in pelvis, and also about duodenum, these areas being separated by a middle zone, relatively free from peritonitis; perforation, 0.5 inch in diameter, 0.7 inch from the pylorus, in the upper wall of the duodenum.[1]

[4] Perry and Shaw: Guy's Hospital Report, 1893, vol. i., p. 261.

[5] Lockwood: Lancet, 1894, vol. ii., p. 964.

No. 10. Male, aged sixty-one, with a long history of gastric ulcer, with epigastric pain and vomiting, never of blood. Sudden pain occurred in right hypochondrium, with collapse. Diagnosis, perforation of gastric ulcer. Operation in four hours fifteen minutes. Perforation in duodenum, anterior wall, 0.7 inch from pylorus, sutured; thorough washing, drainage. Death in six days. Autopsy showed suture tight; a second ulcer in the back of the duodenum, non-perforating; purulent fluid behind liver and in pelvis.[2]

No. 11. Male, aged twenty-eight, in good health. One hour after a movement of the bowels, while lifting a barrel from a dray, felt a sudden pain across the abdomen like a knife; vomiting immediately began and continued. .Third day fecal vomiting occurred; pain especially on right side; pulse, rapid; temperature, 100.6° F.; respiration, rapid; cold sweat. Diagnosis, intestinal obstruction. Operation in sixty-two hours. Subumbilical incision gave vent to a large amount of sero-pus with a fecal odor; cæcum, appendix, hernial openings, and intestine in pelvis examined; incision prolonged upward; perforation as "big as a florin," in anterior wall of duodenum, one inch from pylorus, pared and closed with six or eight Lembert stitches. Area covered by omentum; irrigation; drainage in pelvis. Death in three hours. No autopsy.[3]

No. 12. Female, aged twenty-seven. For a fortnight had epigastric pain, and constipation for seven or eight days; treated for indigestion. Sudden pain in epigastrium and collapse; vomiting frequently repeated. Thirty hours later, slight tympanites; abdomen uniformly tender; pain most marked in epigastrium; vomiting; respiration rapid and irregular; pulse, 120; temperature, 100.6° F.; diagnosis, general peritonitis from mechanical obstruction. Operation in thirty hours (about). Subumbilical incision gave vent to fluid and fibrin; intestinal coils were congested; no lesion found; incision prolonged upward; gas noticed near gall bladder; perforation of duodenum 0.7 inch from pylorus; surrounding induration incised; suture; irrigation; sponging; no drainage. Nothing was taken by mouth for seventeen days. Recovery occurred. Two months later symptoms of obstruction were shown; operation on third day; adhesions which obstructed the ileum a short distance above the cæcum were freed. Death took place from perforation of the wall of the ileum just above the obstruction. The suture of the duodenum was smooth and thin.[4]

No. 13. Male, aged thirty-five, of alcoholic habit. Upon going to work he was attacked by sudden abdominal pain and vomiting; pain and nausea continued, though vomiting ceased. Thirty hours later the patient lay with hollow eyes, alternately extending and drawing up his legs as paroxysms of pain came on. Nothing had passed by anus. There was tympanites except for dulness in the right iliac region, where pressure was painful. No tumor could be made out. Temperature, 37.9° C. (100° F.); pulse, 104 and small. Operation by Brissaud, fifty-one hours after the attack, December 14, 1893. An incision was made over the appendix, giving vent to a great quantity of fecal matter. The appendix was not seen; drainage. Death in a few hours. Autopsy showed general peritonitis, and a fusiform collection of pus from the liver to the right iliac region. There was perforation of an ulcer in the anterior wall of the duodenum, just below the pylorus.[1]

No. 14. Male. After a debauch the patient was attacked with a sharp pain in the right side of the abdomen. Forty-eight hours later there was general tympanites, dulness over a tumor in the right iliac region, and collapse. Operation in fifty-three hours as for appendicitis; from the incision pus and milky fluid escaped in large amounts. Irrigation and drainage; death. Autopsy showed a perforated duodenal ulcer, the sac about the cæcum containing much of the milk and food which had been taken during illness.[2]

No. 15. Male, aged twenty. Slight indigestion. While at the theatre a sudden attack of severe pain occurred in the epigastrium with tenderness; no vomiting; passage of flatus; slight tympanites. Temperature, 96° F.; pulse, 100. On the second day greenish vomiting, becoming fecaloid; obstipation; rapidly increasing tympanites; tenderness in the cæcal region. Diagnosis of appendicitis. Operation in about sixty hours. Gas without odor; thin, purulent fluid, and lymph in peritoneal cavity. Perforation not found; intestines washed; abdomen closed. Death in twenty-four hours. Perforation was in anterior aspect of first portion of duodenum.[3]

No. 16. Male, aged twenty-three. Had an attack of sudden pain, vomiting, and obstipation three years previous; an acute attack of pain and vomiting lasting five days. There were two movements of the bowels in this period. When seen on the sixth day, there were marked tympanites and a very rapid pulse, not much tenderness, and pain in the cæcal region. Diagnosis of appendicitis. An incision about one hundred and five hours after attack allowed odorless gas and thin pus to escape. The intestinal coils were covered with lymph, and greatly distended. An incision into the jejunum permitted several pints of fluid to escape. Perforation was not found. Abdomen was washed and drained. Death in twenty-two hours. Autopsy: There was a small perforation of the anterior wall of the duodenum, one-half an inch below the pylorus. At the same distance, there was in the posterior wall the scar of a healed ulcer.[4]

No. 17. Male, aged twenty-eight, hard drinker. Had sudden abdominal pain accompanied by vomiting. Two days later admitted to hospital with general abdominal distention and tenderness, but no loss of liver dulness. Temperature, 103° F.; respiration, 20; pulse, 120. On the third day a liberal median incision revealed a general peritonitis, with a small amount of fluid; cause not found. Rapid irrigation and drainage. Death three days after operation. Autopsy showed a sharply defined ulcer in the third part of the duodenum, in its posterior wall. The ulcer had for its base the pancreas, whose tissues were necrotic and infiltrated with pus. The suppuration had extended as far as the jejunum, and had there entered the general peritoneal cavity.[5]

[5] Bolton: MEDICAL RECORD, 1900, vol. lvii., p 494.

No. 18. Male, aged thirty-five, a hard drinker, with history of a similar attack thirteen years previous. For a few days there was a severe abdominal pain accompanied by vomiting. Was admitted to the hospital with very great general tenderness, no distention, and a temperature of 102° F. The symptoms improved until the fourth day after admission, and then signs of a rapidly spreading peritonitis were manifest. Diagnosis, appendicitis. Incision made on the fourth day over the appendix showed that organ to be normal. General peritonitis was present and a large quantity of odorless fluid was in the abdomen. Drainage. Death in a few hours. Autopsy showed a perforation in the superior wall of the first portion of the duodenum just beyond the pylorus. The gut was adherent to the liver by recent fibrin. There was also the scar of an old healed ulcer.[1]

No. 19. Male, aged fifty-six. Had a long history of gastritis and of diarrhœa which was sometimes bloody. Acute attack of pain, four hours after dinner; constant vomiting; collapse. The usual lavage failed to give relief and the water did not return readily. Morphine administered; passage of gas per anum. The next day symptoms disappeared, then returned with vigor. Stool after enema. The second day there was again a remission and again a relapse toward night. Dulness and pain were most marked in the right iliac fossa. Pulse, 112; temperature, 38.2° C. The third day there was still iliac tumefaction; marked sepsis; pulse, 160. Operation sixty-six hours after attack. Incision over appendix, which was thought to be the origin of the disease, allowed the escape of three pints of reddish purulent fluid with fibrin masses. The peritonitis appeared limited, and it was judged best not to break up the adhesions to find the perforation. Douche and drainage. Death nine hours after operation. Autopsy showed an ulcer just below the pylorus, occupying two-thirds of the circumference of the duodenum, the anterior wall not being involved. The perforation was on the postero-external surface.[2]

No. 20. Male, aged thirty-three. No previous gastric trouble. Sudden colicky pain in right hypochondrium; collapse; no defecation nor passage of wind. Following day, tympanites; liver dulness absent; temperature, 100° F.; pulse, 122; respiration, 38. Operation in twenty-five hours. Incision was made in median line; purulo-fibrinous peritonitis; gas and fluid from duodenal region; perforation sutured by two rows of stitches; intestines cleaned by moist gauze; no drainage. Recovery after bronchitis; primary union of wound. Patient was seen four years later, in good health.[3]

No. 21. Male, aged thirty-five, a hard drinker. Had sudden severe abdominal pain, without vomiting. Admitted to the hospital eight hours later with a tense abdominal wall, and tenderness over the gall bladder. The pulse was 90, and there was no fever. Later the temperature rose, and distention with obliteration of the liver dulness developed. Diagnosis, appendicitis. Operation in twenty hours. Incision made over appendix, which was normal. A well-marked general peritonitis was present, but the patient's condition prevented further search. Death in twenty-four hours. Autopsy showed a perforation of the duodenum in the posterior wall, one and one-quarter inches from the pylorus, and a second non-perforating ulcer lower down.[4]

No. 22. Male, aged fifty-two. Had an attack of acute pain in epigastrium with obstipation and tympanites, six years previous. Recovery in six weeks. Had more or less pain since. Acute attack of severe pain about pylorus, later extending downward and backward. Absolute obstipation; tympanites slight on second day and increasing, on third day vomiting of moderate character; temperature, 100°–100.5° F. Diagnosis of appendicitis. Operation on fourth day. Intestines were distended and covered with lymph; no pus. Perforation of duodenum into general peritoneal cavity was found and closed; cavity douched with hot water: gauze drain. Thirst and brownish vomiting; rapidly rising temperature. Death on third day after operation. No autopsy.[1]

No. 23. Male. Had sudden epigastric pain while at work, followed by vomiting, tympanites, and loss of liver dulness. Operation in about thirty hours. Perforation in anterior wall of first portion was found and sutured. Gas and yellowish fluid in peritoneal cavity. Flushing with hot water; drainage for twenty-four hours. During convalescence return of symptoms necessitated a second laparotomy. Only adhesions of liver to diaphragm were found. A needle thrust through eighth intercostal space into these drew a drop of pus. A mural abscess formed later which probably caused the above recurrence of symptoms. Recovery.[2]

No. 24. Male, aged fifty, who for ten or fifteen years had pain after meals, with vomiting and bloody stools; last hemorrhage seven months before entrance to hospital. Emaciated and anæmic on entrance; stools were black. Diagnosis of ulcus ventriculi. Two days later sudden pain in right hypochondrium, with retracted abdomen. Temperature, 100° F.; pulse rate normal. The signs of peritonitis with feelings of distention increasing, laparotomy was performed, twelve hours after the attack. A long incision was made above umbilicus with cross-cut to the left and right; stomach and duodenum were examined and fluid like coffee-grounds was squeezed from its posterior region by pressure, but no perforation could be made out. Duodenum, stomach, and colon were sutured together to protect the general peritoneal cavity. Cavity was irrigated and wiped, and drained at epigastrium and through pelvis. Recovery. Six months later he was in good condition, as far as duodenal ulcer went; still had chronic gastritis. Death in eight months from operation for suppurative peritonitis. Autopsy showed a new perforation in the posterior wall at the beginning of the second portion of the duodenum.[3]

No. 25. Male, aged twenty-four years, with no gastric trouble. After a large dinner he felt indisposed for a few minutes. The next morning he rose at six in usual good health and ate his customary breakfast. At the last mouthful of a glass of white wine, he felt a sudden most severe pain and lay down in bed. There was vomiting of food, and afterward incessant vomiting of bile. He described the pain as "not like a general colic, but always in one point here," indicating a spot on the left, midway between the umbilicus and ensiform cartilage. A physician diagnosed volvulus, and tried by enemata and massage to relieve the pain. In five hours vomiting ceased and the pain subsided somewhat and was referred to the lower abdomen. No fecal matter or gas passed the anus. There was no tympanites nor difficulty in passing water. Sixteen hours after the attack he was admitted to the hospital. The abdomen was retracted and board-like; the pain was less and vomiting had ceased. There was costal respiration, and the appearance of the face indicated severe abdominal trouble; the nose was pinched, the eyes were sunken, the hands clammy, and the patient was in a half stupor. Diagnosis was thought to lie between appendicitis and duodenal perforation. Nineteen hours after the attack an incision was made in the median line from the pubis to above the umbilicus. The abdomen contained non-feculent fluid, and there were light adhesions on the intestinal coils. Appendix was normal; no intestinal lesion; pelvis normal. Incision was prolonged upward and stomach searched; gas was found escaping from under liver, and perforation near pylorus on anterior surface of duodenum sutured. Abdomen was wiped and drained from site of duodenum. Several saline injections were given, amounting to 4,200 c.c. in all. Death in twenty hours from peritonitis; suture tight.[1]

No. 26. Male, aged twenty-six; health perfect, never had any gastric symptoms. Two hours after his usual light breakfast, while making a slight effort to open a sack, the patient experienced an intense pain in the left side of his abdomen. He was taken almost at once to a hospital. Diagnosis of appendicitis; treatment by ice and opium. Following day had a feeble pulse, without fever; abdomen distending; tenderness in left iliac fossa. On second day vomiting set in, becoming bloody and bilious. About fifty-six hours after the attack, Sebileau made an incision as for appendicitis, permitting the escape of non-feculent fluid, like bouillon. The appendix was normal. The patient was already collapsed, and nothing further was done, except to drain with gauze and give a saline injection. Death took place after incessant vomiting in thirty hours. Autopsy: The abdomen contained fluid. There was general peritonitis; perforation in the anterior wall of the duodenum, 1 cm. from the pylorus.[2]

No. 27. Male. An attack of sudden pain like lead colic. Incision from the ensiform downward. There was food under the liver, and a perforation was found in the first part of the duodenum, and sutured. Death in twelve hours.[3]

No. 28. Male, policeman, of alcoholic habit and history of gastric attack. While on duty the patient had a sudden attack of pain which made him writhe in agony. His bowels had moved a short time before. When seen soon after, the abdomen was retracted, as hard as a board, excessively tender, especially under the ribs and in the right flank. Diagnosis of hepatic colic. Compresses were applied and morphine administered. The following day he felt better. An injection resulted in a large stool. Milk and Vichy were administered. There was no fever, nor much pain, but the abdomen was still retracted. Thirty hours after the attack vomiting set in, soon becoming bilious. The abdomen swelled and the patient was taken to a hospital. Diagnosis, appendicitis, intestinal obstruction, or volvulus. Abdomen was opened forty-eight hours after the attack; nothing but general peritonitis discovered. Dieulafoy, operator. Death occurred in one hour. Autopsy showed a perforation of the duodenum in the anterior wall just below the pylorus.[4]

No. 29. Female, aged twenty-five, servant, giving a history of gastric trouble with vomiting, but never of blood. An increase of gastric pain, with general tenderness and abdominal swelling, was followed four days later by marked distention. Palpation showed the greatest tenderness to be in the cæcal region. There was no fever. A needle thrust into the right iliac fossa brought out gas, and an odorless fluid containing flakes of fibrin. An incision was made over the appendix, which was congested. There was general peritonitis. Death occurred in four days from the operation. Autopsy showed pus in the pelvis and about the duodenum, in the lower wall of which, close to the pylorus, there was a perforating ulcer. A second ulcer was situated in the posterior wall.[1]

No. 30. Female, aged thirty-four years, servant, with a history of gastric troubles for twenty years, with frequent vomiting of blood; last attack was one week before admission to the hospital, the vomiting being followed by bloody stools. Pulse, 84, regular, strong; rectal temperature, 98.6° F. Maximum pain was midway between ensiform and umbilicus to the right of the median line. Ice-bag applied on abdomen; nothing but ice given by mouth. Next day pain involved the whole right side; was relieved by morphine, but recurred with vomiting. A small pulse of 106, and cold sweat. More morphine was given. Two hours later the pulse was 130; there was tenderness all over the abdomen, with œdema in the epigastrium. Diagnosis, gastric ulcer. Laparotomy two days after admission to the hospital (thought by the operator to be "at least fifteen hours after perforation"), through the left rectus above the umbilicus; gas and fluid escaped; no adhesions; general peritonitis. Perforation at pylorus, thought to be in the lesser curvature, was sutured. Abundant irrigation; gauze drainage; 700 c.c. saline solution injected. Death twenty-four hours after operation. Autopsy showed perforation in the superior wall of the duodenum near the pylorus. The suture was perfect.[2]

No. 31. Female, aged fifty-four years, with history of indigestion; no bloody vomiting. A sudden attack of pain and vomiting, not of blood, followed by a large bloody stool and several small ones of a tarry character, was succeeded eighteen days later by a second attack. There were tenderness and resistance to the right of the median line above the umbilicus; no fever. Laxatives and enemata relieved the abdomen of gas and fecal matter, and the area of resistance became a well-defined tumor. Nine days after the last attack an incision was made through the right rectus muscle, and in separating the abdominal wall from the viscera several small abscesses were opened, and through one of these gas and gastric contents escaped. Perforation was readily found and closed. It was at the pylorus and thought to be in the stomach. The gall bladder was opened and eight stones were removed. Most of the omentum was excised. Iodoform-gauze drains were inserted. Death took place in five weeks. Autopsy showed that the abdominal condition was perfect. Death was due to pulmonary thrombosis, infarction from saphenous thrombosis. The sutured ulcer had healed. Two others in the duodenum had not perforated.[3]

No. 32. Male, aged thirty-seven, shoemaker, with nausea and vomiting and indigestion more or less for years. One morning he awoke feeling perfectly well. On sitting up in bed he was seized by a terrible pain in the umbilicus and to the right side, lasting several hours and followed by vomiting. Enemata resulted in several small stools. The next day he was taken twenty-five miles in a sleigh to the hospital, where he arrived with respiration 26; pulse, 140; temperature, 102.5° F., but free from pain while at rest; tenderness in left iliac fossa and in the right hypochondrium, and over right rectus muscle. Stomach and bowels were washed out. Diagnosis of duodenal ulcer or appendicitis. Sixty hours after the attack an incision was made in the median line, mostly below the umbilicus. Fluid and gas and fibrin escaping mostly from above, the cut was extended upward and the right rectus was cut across. A perforation into which the index finger passed was found in the anterior superior wall of the duodenum near the pylorus. It was sutured and the cavity washed out with water at a temperature of about 45° C., wiped out, and drained in both loins as well as about duodenum and liver. Compresses wrung out of hot saline solution were placed in the wound, which was left open. The pulse and temperature gradually rose, and in spite of 1,150 c.c. of salt solution injected into a vein, the patient died in twenty-six hours after operation. Autopsy showed fibrous peritonitis without fluid. The suture was firm. There was an abscess between the stomach and colon.[1]

[2] Lennander: *Ibid.*

[3] Lennander: *Ibid.*

No. 33. Male, aged forty-six. While lifting a heavy weight, he felt something snap, and immediately afterward there was intense pain (locality not given), which soon spread to the whole abdomen. Four days later he entered the hospital, not having passed gas or fecal matter per anum. There was no localized pain, but pressure was everywhere painful; no tumor or fluctuation. The patient had not vomited but had a hiccough. Pulse, irregular, 110; temperature, 99° F. A diagnosis of intestinal obstruction was made, and castor oil was given in small doses every hour. The next day there was great prostration, with choreic movements. Five days after the attack the abdomen was opened by a median incision from pubis to ensiform cartilage, with a cross-cut through the right rectus muscle. There was a general peritonitis with pus and membranes all over, but especially in the pelvis. At the pylorus on the superior surface was a large perforation which was sewed with difficulty, and the abdomen was flushed and closed. Death occurred two hours after the operation.[2]

No. 34. Female, aged thirty, with a history of indigestion and some epigastric pains. While eating breakfast she was seized with terrible pain in the epigastrium and left the restaurant for a seat in the park close by. She was taken at once to a hospital. In six hours the pain was general and vomiting set in. The following morning she was worse, without stools or passage of gas, and scanty urine. The condition grew rapidly worse, with rapid pulse, subnormal temperature, tympanites, and loss of liver dulness. A diagnosis of perforation, probably of the stomach, was followed by operation, twenty-eight hours after the attack. Incision above the umbilicus gave escape to gas and a quart of bile and purulent fluid. Stomach and biliary tract were normal, and perforation was found in the right side of the second portion of the duodenum. Opening was sutured and abdomen closed over a rubber drain to duodenum. Death in fourteen hours. Autopsy showed perforation a little below and to the right of the opening of the common duct, which explained why the bile flowed so freely into the abdomen. The closure was perfect. There was a second ulcer a little below the first which had not perforated.[3]

No. 35. Male, aged twenty-three, a soldier with history of numerous sprees before he entered the army. During a march he took a cup of coffee, and almost immediately he was overcome by pain in the epigastrium and right hypochondrium, streaming into the right shoulder. He was nauseated but did not vomit. There were tenderness and muscular contraction on pressure, especially on the right side. An enema produced a normal dejection. The pain spread over the whole upper part of the abdomen, accompanied with a certain amount of distention, constant vomiting of greenish fluid, and a partial disappearance of the liver dulness. Incision made above the umbilicus forty-eight hours after the attack. General peritonitis. Intestine was overhauled, then liver examined. Bubbling at its base led to the discovery of the duodenal perforation in the postero-superior wall of the first portion of the duodenum. The right rectus was divided to give room for suturing, but the stitches would not hold, and the perforation, of a size to admit the little finger, was walled off from the peritoneal cavity by omentum sutured above and below it. Death in thirty-six hours of general peritonitis. There were no other lesions found at autopsy.[1]

No. 36. Male, aged twenty-two; always perfectly healthy. Had an acute attack of intense pain and vomiting three hours after supper; pain referred to the umbilicus and right side. On the following morning temperature was 101° F.; pulse, 120; respiration, 42; moderate tympanites. Lower edge of liver dulness was two inches above the costal margin; tenderness most marked in the epigastrium, and on the right side of abdomen. Diagnosis of peritonitis, probably due to appendicitis. Operation fifteen hours after the onset of attack; incision made over appendix. General sero-purulent peritonitis was found. The appendix appeared normal but was excised. A second incision above umbilicus revealed, after careful search, a one-quarter-inch opening in the anterior wall of the first portion of the duodenum, close to the hepatic ligament. It was in the centre of an indurated area, and on account of its deep situation no excision was made. It was sutured, and the peritoneum cleaned with gauze; abdomen closed over iodoform gauze drain. Recovery took place with severe illness.[2]

No. 37. Male, aged thirty-eight, with history of attacks of intense pain in the epigastrium three or four hours after meals, without nausea or vomiting. While in his usual good health, he suffered an acute attack of violent pain in the epigastrium with collapse. He recovered somewhat and then grew gradually worse, with vomiting on the third day; no movement of the bowels for a week before the attack. On the third day, temperature, 100° F.; pulse, 99; respiration, 30. Face was drawn; abdomen distended with gas; dull in flanks; liver dulness absent. Operation about seventy-two hours after onset of acute symptoms. Through an incision in the median line, much gas and thin greenish-yellow purulent fluid escaped, with flakes of lymph; appendix was normal. A search over the intestine showed the perforation to be in the anterior wall of the duodenum near the pylorus. It was sutured and the abdomen swabbed out. The operation lasted two and a half hours; afterward one quart of saline solution was injected into the basilic vein. Death took place in eight hours. The peritoneal cavity was dry, except six ounces of pus between the diaphragm and liver. The suture was tight, and adhesions had already formed around it.[3]

No. 38.—Male, aged thirty, with a history of dyspepsia. While stooping to draw off his boots, the patient suffered a severe pain in his stomach which stretched him out. The following day an enema was without result. The abdomen was swollen and painful, the pain being all about the umbilicus, the urine scanty, and the pulse 120. About twenty-seven hours after the accident an incision was made in the median line at the umbilicus. The intestinal coils were distended and red. A mass of fecal matter seemed to clog the lumen, and was pushed along for a couple of yards. A suspicious yellow fluid was in the peritoneal cavity, and pus pas found in the pelvis. The appendix was normal. The abdomen was flushed with boric-acid solution and closed. The vomiting ceased; gas and a great quantity of fæces passed, and the abdomen became soft. Five days later the patient was attacked with dyspnœa, and double pneumonia developed. Death took place in nine days after the operation. There were numerous pus foci in the abdomen, and a perforation of the duodenum partly shut in by adhesions.[1]

[3] Whipple: Brit. Med. Jour., 1898, vol. ii., p. 1429.

No. 39.—Female, aged seventeen, and fairly healthy; had rarely suffered from indigestion. One week before perforation occurred, there had been indefinite pain in the abdomen for which she consulted a physician, who feared a beginning attack of appendicitis. About three hours after eating a hearty supper, while walking rapidly, she was seized with a violent pain above the umbilicus. Prostration followed, with rapid pulse, subnormal temperature, vomiting, and rigid abdominal muscles. Infusion of saline solution and stimulants failing to improve the patient's condition, operation was performed twelve hours after the beginning of the attack; incision as for appendicitis. Appendix and pelvic organs were normal, as was the small intestine. In the upper part of the abdomen there was a good deal of lymph and greenish fluid. The perforation of the duodenum was in the anterior wall of its third portion, and was about the size of a goose-quill, and surrounded for about an inch by an indurated area. Fluid was freely escaping. Direct sutures would not hold, so a purse-string was inserted, and afterward other peritoneal sutures. In this way the opening was firmly closed. Lymph and fluid were wiped away, and the abdomen was flushed with a great quantity of hot saline solution. Numerous gauze drains were inserted. Convalescence was slow, as it was a long time before the suppurating tracts, where the drains had lain for a week, had healed, but the patient ultimately recovered completely.[2]

No. 40.—Male, aged thirty. Sudden pain in abdomen occurred, followed by shock and toxic symptoms. Operation was done thirty-six hours later as for appendicitis. Perforation was found in first portion of duodenum. No blood or food in peritoneal cavity. Death occurred in a few hours.[3]

No. 41.—Male, aged forty, was seized with pain while at work, followed by shock and toxic symptoms and great tympanites. Operation in twenty hours. Perforation was found in first portion of duodenum, no blood or food having escaped. Death took place in a few hours.[4]

No. 42.—Male, aged thirty-eight. A supposed pulmonary abscess was opened and a large quantity of pus escaped. Two weeks later an abscess formed in the groin and was opened. Later the abdomen was opened for appendicitis, and a quart of creamy pus containing streptococci escaped. Death followed. Autopsy showed two ulcers near pyloric ring, one in the duodenum, the base of which had healed over, and one in the stomach perforated. There were numerous pus pockets in the abdomen, one in the head of the pancreas being the original one apparently.[5]

No. 43.—Male, aged twenty-nine, alcoholic. For three years had morning vomiting. Following a long spree he felt umbilical pain, and vomited and had a chill. The next day the abdomen was moderately distended and rigid. Diagnosis of general peritonitis from appendicitis. Operation was done one to two days after attack. About one quart of fluid and fibrin escaped. Appendix was amputated. Death occurred in thirty hours. Autopsy revealed perforation in superior anterior surface of duodenum near pylorus.[1]

No. 44.—Male, aged thirty, with history of gastric disturbance; no hæmatemesis. Had sudden severe epigastric pain, with chill, fever, and repeated vomiting and great prostration. No blood passed by mouth or rectum. Gradually increasing distention and tenderness were noted. Four days later, April 30, 1900, he entered the New York Hospital; the abdomen was generally swelled, but not presenting any special points of tenderness or dulness. Liver dulness was absent. Patient had a double hernia, and in the right hernial sac intestine was to be felt. Temperature, 104° F.; pulse, 140. Median incision was made with umbilicus in centre. Nothing abnormal was found at the internal rings or about the cæcum. From a one-fourth-inch perforation in the antero-superior wall of the duodenum close to the pylorus, brandy and water was found escaping. Closed with a double row of sutures; thorough washing of intestines and cavity; saline transfusion of seventy-five ounces, etc. Death occurred in a few hours. Operator, Weir. Case not previously reported.

No. 45.—Male, aged twenty-seven, always healthy but a steady drinker. Had colicky pain for four days, above the umbilicus on the right side. Bowels moved daily and he kept on working. Then suddenly he had severe pain three inches above navel, and a little to right of median line, with chill, no nausea. Nine hours later, pulse, 80, respiration, 20; temperature, 101.5° F. March 28, 1899, abdomen was opened; ten hours after had sudden pain, along right semilunar line above and below umbilicus, bile-stained fluid escaped. Appendix was examined as a matter of precaution and found normal. Incision extended upward to ribs. There was a perforation of duodenum on anterior surface, descending portion, big enough to admit 26 F. sound, through which bile and intestinal contents were escaping. All organs in the vicinity showed signs of irritation and so were washed with saline solution, while opening was closed by pad. Suture of perforation was done, with repeated flushing of peritoneal cavity without evisceration, and wiping with dry gauze, gauze drain to ulcer; wound elsewhere closed. No shock. Patient was fed by rectum for forty-eight hours. Temperature on following day 101° F. There was infection of skin stitches, which were removed. Recovery was otherwise uneventful and perfect.[2]

No. 46.—Female, aged twenty-five. She had a sudden attack of umbilical pain, with rigor and slight vomiting; on following day, pain at pylorus and blood passed per rectum. Temperature then and later 101° F. or less. Attack gradually subsided, but in two weeks a similar slighter attack occurred. Later a fluctuating tumor was found in region of gall bladder, gradually increasing in size until it occupied the whole right upper quadrant of abdomen. It was crossed by resonant colon, elsewhere dull on percussion. Diagnosis was hydronephrosis. Through lumbar incision a quart or more of clear amber, odorless fluid drawn off. Cyst reached from liver to iliac crest, and backward to spine. Kidney was not felt. Wound was stuffed with gauze, which next day was soaked with sour fluid. On third day food was noticed in dressing. Patient developed acute bronchitis and died on fifth day. Autopsy showed duodenal perforation three and one-half inches from pylorus forming this retroperitoneal cyst below right kidney and reaching behind duodenum as far as pancreas.[3]

No. 47.—No history was given. Incision made from ensiform cartilage to pubis; ulcer found at back of the duodenum and with difficulty stitched. Patient collapsed and the abdominal wound was hastily closed. Death from hemorrhage from a vessel in the abdominal wound.[1]

[2] Johnson; Am. Surg., 1899, vol. xxx., p. 634.

[3] Wright and Bury: Lancet, 1899, vol. ii., p. 215.

No. 48.—Patient was neurasthenic and little attention was paid to his statement that he had great pain. Operation on the fifth day, when liver dulness was entirely obscured. Gas had escaped from the perforation, but no fecal matter; the ulcer was therefore sutured and the abdominal wound closed without drainage. Death on the third day from infection leading from the site of perforation to the pelvis. Suture firm. The operator thought that pelvic drainage might have saved this patient.[2]

No. 49.—Male, aged fifty-two years. Epigastric pain of three days' duration was followed by violent exacerbation. There was no vomiting. Six hours later the abdomen was tense, rigid, almost motionless, with complete absence of liver dulness in the line of the nipple. A diagnosis of perforated duodenal ulcer was made and operation decided upon. Ten hours after the attack an incision was made through the right rectus, and a clean-cut perforation was found at the junction of the first and second portions of the duodenum. There was intestinal injection but no well-marked peritonitis. The perforation was closed with two rows of sutures; the intestines were brought out and washed with sterile water; a gauze slip was passed to the site of the ulceration, and the cavity of the abdomen was otherwise closed. Recovery was uneventful. The gauze plug was removed on the second day, and the bowels moved on the third day.[3]

No. 50.—Male, aged twenty. Seven months previously he had an attack of epigastric pain and vomiting lasting two weeks; sudden severe pain in the right side of the abdomen, accompanied by vomiting. A few hours later the tenderness was greatest over the appendix. Temperature, 102° F.; respiration, 48; pulse, 118. Diagnosis, appendicitis. Twenty hours after the attack, an incision over the appendix allowed the escape of a quantity of odorless gas and fluid. On account of feeble condition, further operative attempt was abandoned. Death in twenty-four hours. Autopsy showed a perforation in the duodenum, anterior wall, just beyond the pylorus.[4]

No. 51.—Male, aged forty-five, a moderate drinker. Four years previously he had a similar attack. While in perfect health he was seized with severe pain in the right side of the abdomen, referred to the iliac region. A few hours later the abdominal wall was tense, without distention or loss of liver dulness; tenderness over the appendix. Temperature, 100° F; respiration, 32; pulse, 104. Diagnosis, appendicitis. Twenty-two hours after the attack an incision over the appendix evacuated considerable turbid serum. The appendix was normal. The peritonitis was most marked on the right side, and was followed up the colon to the hepatic region, but no cause for it could be found. The whole abdomen was flushed and drains were placed in the duodenal region and in the pelvis. Death occurred in seven days. Autopsy showed a general exudative peritonitis, without free fluid. In the duodenum, anterior wall, just below the plyorus, was a perforated ulcer, with the scar of a healed one.[5]

A PRELIMINARY REPORT ON A NEW AND SIMPLE METHOD OF STERILIZING CATGUT.[1]

By CHARLES A. ELSBERG, M.D.,
ATTENDING SURGEON, MT. SINAI HOSPITAL DISPENSARY.

EVER since the time that the absorbable ligature was introduced into surgical procedure by Lister, catgut has held a prominent place in our surgical armamentarium. There has been, and still is, however, much difference of opinion regarding the relative value of the non-absorbable ligatures—silk, silkworm gut, silver wire, and the more recently recommended celluloid thread, and the absorbable ligatures—catgut, kangaroo tendon, etc. Without giving an account of the indications for the use of the one or the other, it suffices to state in this place that the use of catgut has been much curtailed because of the difficulty—by some considered an impossibility—of always sterilizing it perfectly. For well-known reasons the ordinary method of boiling is not applicable to catgut. Immersion for a short time in strong antiseptic solutions may render the catgut sterile, but it becomes hard, fragile, and useless. Prolonged immersion in dilute solutions of antiseptics has been found to suffice in most cases and has been extensively used. In this class of methods may be placed the catgut of Lister, von Bergmann, Braatz, the juniper-oil catgut of Kocher, the silver catgut of Credé, and the chromicized catgut of Macewen. Sterilization by dry heat has been recommended by Reverdin, Kümmel, Lauenstein, and others, but time, care, and a special heating oven are required.

A number of boiling methods have been recommended: the cumol method of Krönig, the xylol method of Brunner, the alcohol method of Dowd and of Fowler, the carbolic-acid alcohol method of Saul, the more recent formalin method of Cunningham and of Hofmeister, etc. In most of these procedures the catgut is first freed of its fat and then boiled in a special solution for various lengths of time. Most of the fluids that have been used are inflammable or their vapors are inflammable, and some of them have a low boiling-point so that they have to be boiled under pressure. As a result a more or less elaborate apparatus is necessary; hence the procedures are not available for general use. Large drug houses that prepare sterile catgut for the market use one or the other of these methods. The immersion of the catgut in a dilute solution of formalin (two to four per cent.) fixes the albuminous substances so that the catgut can then be boiled in water or in decinormal salt solution without injury to it. Catgut prepared in this manner is often of very good quality. But under the same conditions of preparation it is sometimes soft and strong, at other times hard and fragile. Considerable practical experience is necessary, and even then one cannot succeed in obtaining uniform results with the formalin method. Formalin catgut is absorbed somewhat more slowly than catgut prepared by other methods.

We have, therefore, up to the present time no absolutely satisfactory and practical means of sterilizing catgut. Prolonged immersion in dilute solutions of antiseptics requires time, and is not always certain; sterilization by dry heat is impracticable; most of the boiling methods require a complicated apparatus; the formalin method does not give constant results even in experienced hands.

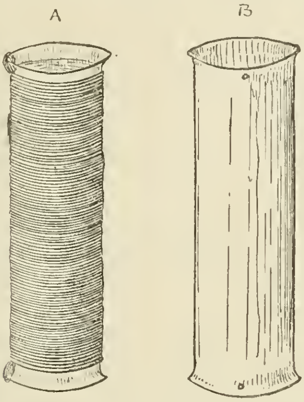
The requisites for a good catgut are: (1) sterility; (2) strength; (3) softness and pliability.

In a series of investigations on the preparation of catgut and other suture materials, the writer had occasion to apply to the work a chemical principle seldom described but much used in chemistry—that animal substances are insoluble in those solutions which precipitate the animal substances themselves. Thus ammonium sulphate precipitates albumin, and therefore albumin is insoluble in solutions of this chemical. Among other substances ammonium sulphate, one of the most perfect precipitants of albumin known to chemistry, was used; it was discovered that this material has some hitherto unrecognized properties. One of these properties is made use of in the method of sterilizing catgut now to be described.

---

[1] Read at the meeting of the Surgical Section of the Academy of Medicine, April 9, 1900.

The fatty matter is removed from the catgut by immersing the latter in ether or chloroform for from twelve to forty-eight hours. It is advisable to use a mixture of chloroform one part, ether two parts, as such a mixture seems to have greater penetrating power; besides chloroform is an antiseptic. A stock of catgut from which the fat has been removed in this manner may be kept on hand in the dry state, the ether and chloroform mixture having been allowed to evaporate, and the catgut kept in a clean receptacle. When the catgut is to be sterilized, it is wound in a single layer and as tightly as can be done with ease with the fingers on spools or frames of any convenient size and shape. I have found the spools here pictured (see figure) useful; they are of a convenient size, and from five to ten yards of catgut can be wound in a single layer on them. The spools are then boiled from ten to thirty minutes in a hot saturated solution of ammonium sulphate in water. This solution is made by adding chemically pure ammonium sulphate to boiling water until the latter is saturated or almost saturated. The solution boils at 106°–108° C. or 220°–226° F.—a high boiling-point, as will be observed.



Glass Spools for Use in the Sterilization of Catgut by the Ammonium-Sulphate Method. *A*, Spool with single layer of catgut wound on it; *B*, spool with perforations at its ends.

When the spools are removed from the boiling solution some of the salt crystallizes upon them. This is at once removed by a moment's immersion and agitation in warm or cold water, carbolic acid, or bichloride solution. The catgut is then ready for use or for preservation in strong alcohol.

Catgut that has been prepared in this manner will be found to have lost none of its physical properties. It is fully as strong as catgut prepared by other methods; indeed, comparative experiments, which it would take too long to detail here, have shown that very fine catgut is stronger after having been boiled in the ammonium-sulphate solution than after it has been prepared by other methods. The catgut does not swell up; it remains of the same thickness as the raw material. It is readily absorbed in the tissues of the body, and its absorption takes place between the fourth and the eighth days.

Bacteriological experiments have shown conclusively that catgut prepared by this method is always sterile after five minutes of boiling. The accompanying table gives a summary of some of my experiments and results. As will be seen in the table, the anthrax catgut was always rendered sterile in less than five minutes and the staphylococcus catgut in less than three minutes.

Instead of in plain water the ammonium sulphate can be dissolved in one or two per cent. watery carbolic-acid solution, or in 0.1 to 0.5 per cent. watery chromic-acid solution. The subjoined table shows how much less time is required to sterilize the catgut when two-per-cent. carbolic-acid solution is used instead of plain water. Thus, while it takes between three and five minutes to sterilize catgut that has been infected with anthrax spores when boiled in the watery solution of ammonium sulphate, it takes from two to three minutes to sterilize it when two-per-cent. carbolic-acid solution is used instead of plain water.

Catgut can be chromicized by boiling in chromic acid of any desirable strength. My experiments in regard to this matter are not as yet completed, but from the results thus far obtained it is probable that catgut can be made more or less absorbable at will, depending upon the strength of the chromic-acid solution used and the length of time of boiling. For general use I have made chromicized catgut by boiling it for twenty to thirty minutes in a saturated solution of ammonium sulphate in 1 . 1,000 chromic-acid solution.

---

[1] Sterile coarse catgut threads were immersed in bouillon cultures of bacteria for twenty-four hours, and were dried and boiled in the solutions. The threads were then washed in sterile water, cut into short pieces, and dropped into nutrient bouillon. + + = profuse growth, + = growth, — = no growth.

The ammonium-sulphate solution can be used any number of times; the salt crystallizes out unchanged as the solution cools, and redissolves on heating. An excess of ammonium sulphate does no harm. The catgut can be resterilized any number of times by boiling it in the solution for from five to fifteen minutes.

During the last two months catgut prepared in this manner has been used by myself in a number of cases, mostly minor operations, and by several gentlemen in major operations in their services in Mt. Sinai and the City hospitals. The results obtained have been very satisfactory. The catgut was well borne by the tissues; it was absorbed in from four to eight days; it was strong, soft, and pliable—in short, it had all the qualities of a good catgut.

The advantages of this new method of sterilizing catgut are its cheapness (c. p. ammonium sulphate costs from 15 to 25 cents a pound), its availability for general use (no previous experience with the procedure is necessary), the non-inflammability and high boiling-point of the fluid used; its simplicity (nothing need be measured or weighed out); and, above all, the fact that all grades of catgut can be used and no apparatus of any kind is necessary. Any one who desires to prepare sterile catgut for himself need only obtain catgut free from fat or prepare such for himself, and then boil it, wound up on spools in single layers, in a hot saturated solution of ammonium sulphate in one or two per cent. carbolic-acid solution, for from three to five minutes, or in a saturated solution of ammonium sulphate in plain boiling water for from ten to thirty minutes; then the ammonium sulphate is washed off by immersing and agitating the spools for a minute or two in cold or better warm water, carbolic acid, or sublimate solution, and then the catgut is ready for use or for preservation in strong alcohol.

In this preliminary report the theoretical principles on which this method is based are hardly touched on. Upon the same principle, with a little difference in technique, sponges and other surgical materials can be sterilized repeatedly by boiling. The further description and discussion of these matters the writer reserves for future publication.

To recapitulate, the steps of the procedure are the following:

1. Catgut, freed from fat as above described, is tightly wound in single layers on suitable spools.

2. The spools are boiled for from ten to thirty minutes in a hot saturated solution of ammonium sulphate in water, made by adding chemically pure ammonium sulphate to boiling water until no more will dissolve.

3. Two-per-cent. carbolic-acid solution may be substituted for the water if a quicker sterilization (three to ten minutes) is desired; or 1 : 1,000 chromic-acid solution, if the catgut is to be chromicized.

4. The spools are thoroughly washed by agitation for from one to two minutes in cold or better warm sterile water, carbolic acid, or bichloride solution of any strength.

5. The catgut spools are preserved in strong alcohol.

6. For resterilization the catgut spools are boiled for from five to fifteen minutes in any of the solutions, and washed in the same manner as described under 4.

105 East Fifty-seventh Street.

Interesting Case of a Pin Transfixing the Eye.—Christian R. Holmes reports the case of a woman who was struck in the face by the free end of a rug she was shaking, with the result that a pin entered the conjunctiva and penetrated the globe, the head showing superficially to the conjunctiva 2 mm. below the horizontal line, and 5 mm. from the inner corneal margin. There was subretinal hemorrhage where the pin entered the eye, and also where it penetrated the posterior part of the globe. Under cocaine the pin was extracted by means of forceps, without loss of vitreous or of blood, but with difficulty on account of the end having become hooked. Pain and inflammation subsided three hours after the operation.—*The Cincinnati Lancet-Clinic*, March 31, 1900.

Ambulatory Treatment of Fractures.—Charles D. Lockwood defines this treatment as any method that enables the patient to be about in an erect posture—while bony union is taking place—and that materially shortens the period of enforced recumbency. His conclusions are: (1) That orthopedic measures and appliances should be more widely used in the treatment of all bone diseases and fractures; (2) all fractures of the lower limb are adapted at some period of their existence to ambulatory treatment, the time depending upon severity, nature, and site of fracture; (3) this form of treatment does not materially hasten bony union, but it makes it more often attainable; (4) the dangers attending ambulatory treatment are largely theoretical, and may be practically disregarded; (5) the early application of ambulatory apparatus, together with early massage, as practised by the French, is the ideal treatment for fractures.—*Illinois Medical Journal*, April, 1900.

The Early Diagnosis of Idiocy.—J Park West urges careful observation with a view to early diagnosis of this condition in children, because of the great importance of early giving the proper treatment. He mentions many of the physical signs of idiocy, with the differential diagnosis from hydrocephalus. One of the earliest symptoms in congenital cases is abnormal movements, or rather the absence or the slow performance of the constant movements of normal healthy children. Likewise, a great increase in the "normal unrest," as tremor, twitching or jerking, indicates trouble of the nervous system. Congenital idiots grow slowly, both physically and mentally. Defective development and defect in the formation of some part or parts are not unusual.—*Columbus Medical Journal*, March, 1900.

Tuberculous Osteitis of the Patella.—Maurice Gross considers that primary tuberculous osteitis of the patella is of more frequent occurrence than is usually supposed. It is a disease of much gravity, the tuberculous area rapidly perforating the thin posterior cartilaginous layer of the bone, causing a tuberculous arthritis of the knee. If a diagnosis be made sufficienty early in the disease, a relatively simple operation will suffice to check it. The operations which are of value are the following: (1) Scraping out the infected area; (2) ablation of the patella in nearly all cases of disease of this bone, especially in adults. Synovectomy may be done in connection with this procedure. (3) The patella can be removed without interfering with the functions of the knee joint. After total subperiosteal suppression of the patella, it has the power of reproducing itself.—*Revue Médicale de la Suisse Romande*, March 20, 1900.

Experimental Researches in Regard to the Conveyance of Tuberculous Poison from Parent to Child.—Angelo Maffucci concludes that the tuberculous poison is more often passed on to the child than is the bacillus; that it may be conveyed by the ovum, spermatozoön, or placenta; that embryonal intoxication is manifested by imperfect development, abortion, premature labor, death, and cachexia in extra-uterine life. The embryonal tissues resist and often destroy the bacillus, generating a toxin which becomes fixed in them. The children of tuberculous parents are not more susceptible to the tuberculous virus than those of healthy parents, the greater frequency of tuberculosis among them being due to contact and to the possibility of a germ carried from embryonal life rather than to a hereditary predisposition. Good hygienic conditions can overcome hereditary and embryonal tuberculosis.—*Rivista Critica di Clinica Medica*, March 24, 1900.

Cultivation of the Lepra Bacillus.—Juan de Dios Carrasquilla says that Hansen's bacillus may be cultivated in gelatinized human serum when this is sown with lymph taken from a leper by Herman's method. A second culture, identical with the first, may be obtained by transferring to other tubes of gelatinized human serum. The bacillus may also be cultivated in bouillon after previous culture in gelatinized human serum. The bacillus grown in both is aerobic and motile. The optimum temperature is 37° C. The temperature may be reduced to 25° for a few hours without injury, but the bacillus is destroyed at a temperature of 45° C.—*Gaceta Médica Catalana*, February 15, 1900.

A Case of Bilateral Facial Paralysis.—Jolly reports the case of a man forty-four years old who had suffered for nearly twenty years from facial paralysis on both sides. The trouble had followed an injury incurred by being caught by a revolving wheel and thrown violently on to a heap of coal. The patient was unable to wrinkle the forehead, to wink the eyes, or to change the expression of the mouth. The only movements possible were those of the jaw; all the muscles supplied by the facial were paralyzed. One eye was nearly destroyed by the original injury, and the other suffered greatly through its exposure to dust. The nerves were injured in their passage through the petrous portion of the temporal bone, and there must have been a transverse fracture through both these bones.—*Deutsche medicinische Wochenschrift*, March 15, 1900.

The Fate and the Action of Acid Sodium Urate in the Abdominal Cavity and Joints of Rabbits.—As the result of an experimental investigation undertaken for the purpose of determining the alterations induced by acid sodium urate in the tissues and the fate of this substance in the body, His found that this substance, injected into the abdominal cavity and joints of rabbits, excites inflammation, attended with necrosis. This is distinguished from that induced by indifferent foreign bodies by beginning earlier, by its greater intensity and extent, and by extension of the necrosis to adjacent parts. On injecting the urate into the joints the cartilage remains intact, while the synovial membrane and the periarticular structures become inflamed. Acid sodium urate acts in part as a foreign body and in part as a feeble tissue-poison. The toxic action is attributable to the solution of the salt. Within the body the amorphous salt may undergo crystallization. Even considerable amounts of urates are absorbed from the abdominal and articular cavities within eight or ten days at most. In the removal phagocytes participate in an active manner; also uninuclear and multinuclear leucocytes, granulation cells and giant cells. Within these cells the urate is rapidly destroyed, and it can no longer be demonstrated in the regional lymphatic glands. It is probable that the same processes take place in cases of recent gout in human beings, but that in cases of chronic gout the reactive powers of the organism are diminished. In future autopsies in cases of gout attention should be directed to the changes in the recently inflamed parts, and among therapeutic measures vital processes should be taken into consideration in addition to the chemical.—*Deutsches Archiv für klinische Medicin*, Bd. 67, Heft 1 and 2.

Rupture of the Pregnant Uterus.—Alexander Doktor reports the case of a woman, thirty years old, who was brought to the hospital in a state of partial collapse. She had passed through a normal pregnancy and had been in labor for a while, but the pains suddenly ceased after about twenty hours, and the patient's condition became very grave. A diagnosis of rupture of the uterus was made. Cæsarean section was performed, and the patient made a good recovery. The fœtus was a male, weighing nine pounds five ounces, with a large head (fifteen and three-fifth inches in circumference) the bones of which were in great part ossified, and the sutures and fontanelles were narrow.—*Der Frauenarzt*, March 16, 1900.

Human Actinomycosis.—Antonin Poncet gives the results of a study of twenty-six cases. In twenty-one the tumors were situated in the cervico-facial region, one in the pleural region, with perirenal infiltration and secondary nucleus in the breast, two in the cæcal, one in the umbilical, and one in the vesico-ano-rectal region. Out of fifteen of the cases in which the ultimate results of the disease could be traced, there were five deaths, two relapses, and eight temporary cures. The author advises the iodine treatment, but considers its value problematical. He urges great vigilance, early diagnosis, and prompt surgical interference. Mere evacuation is not sufficient, but should be followed by curetting and cauterization.—*Bulletin de l'Académie de Médecine*, March 27, 1900.

Sciatica and its Treatment.—Francesco Tommasoli refers to the various methods of treatment used in this affection, such as the rest cure, injections of antipyrin or carbolic acid, mud baths, electricity, compression, and nerve stretching. He then describes the surgical treatment of the nerve as performed by himself. The usual pre-operatory procedures are followed, and the patient is given an injection of morphine and atropine and anæsthetized. An incision about 8 cm. long is made in the posterior median line of the thigh, between its upper and middle third; the sciatic nerve is seized by the curved index finger of the right hand, and gently pulled until it is lengthened by several centimetres. The wound is then irrigated and dried, and sutured with catgut. The results have been satisfactory in several cases.—*Il Raccoglitore Medico*, March 20, 1900.

Septic Maculo-Papular Erythema in Conjunction with a Follicular Angina.—Karl Dehio says that through clinical observation alone must we expect light to be thrown upon most questions involved in erythema multiforme. He relates a case in a female nurse, twenty-three years old, who after chills had on the third day a temperature of 40.5° C., and pain in swallowing (angina lacunaris). The same night there appeared an erythema upon hands, feet, and neck, disappearing under pressure. This was followed by delirium, increased temperature and pulse, vomiting, increase in size of original dark red maculæ and many new ones, with subsequent change of the central parts into livid red, which on pressure left behind a dark brown pigmentation. Desquamation in large flakes and convalescence set in on the fourteenth day of the fever. He regards the process as an infection akin to the exanthemata.—*St. Petersburger medicinische Wochenschrift*, March 17, 1900.

Progress of Medical Science.

Journal of the American Med. Ass'n, April 28, 1900.

Congenital Aphakia and Irideremia. — Flavel B. Tiffany reports several cases in the same family, and states that congenital aphakia is an exceedingly rare anomaly, being usually accompanied with other serious defects of the eye. Iridodonesis is generally explained by the loss of the crystalline lens, that is, the posterior support of the iris. The writer attributes the trembling of the iris in these cases not only to congenital aphakia, but probably to a weakness of the ciliary body and suspensory ligament, and the dimness of vision to an arrest of development or defect of one or several of the ten layers of the retina. Very curiously, concave glasses gave improvement of vision, showing a high degree of myopia, whereas hypermetropia was expected.

The Smegma Bacillus.—Oscar A. Dahms, among the differential points distinguishing the smegma and syphilis bacilli, says the latter are, as a rule, slender straight or curved rods, while the former are smaller, plump rods. The smegma organisms are more readily decolorized by alcohol. They may also resist the action of acids for two minutes or longer, while the organisms of syphilis are decolorized by acids in thirty to forty seconds. The latter are stained well by Doutrelepont's method, while the smegma bacilli are not. In differentiating the smegma from the tubercle bacillus, Marion Dorset has found that Sudan iii. stains the tubercle bacillus a bright red, while it does not stain the smegma bacillus.

Treatment of Variola by Bichloride Baths.—H. A. Ingalls believes in regard to this treatment that: (1) There is practically no mortality. (2) The suppurative fever can be shortened four to six days if the patient is treated from the onset. (3) A minimum of pitting is secured, and there is an almost entire absence of the characteristic disagreeable odor. (4) The period of desquamation is materially lessened, owing to the thinness of the scab formation. (5) Pain is much reduced, morphine being rarely indicated. (6) Distorting of features is eliminated to a great extent.

Double Inguinal Hernia upon the Same Side; Illustration.—Charles C. Allison describes this case of a man fifty-six years old, operated on February 3, 1900. The hernial protrusion was oblong in shape and extended into the upper part of the scrotum. It was reducible, and its reduction revealed a very marked attenuation of the abdominal muscle over the inguinal region. It is a case of exceeding rarity.

Endothelioma of Gasserian Ganglion: Two Successive Resections of Ganglion—First by Extradural (Hartley-Krause) Operation, and Secondly by Intradural Operation.—By F. X. Dercum, W. W. Keen, and W. G. Spiller.

Peripheral Resection of Fifth Nerve. Three Cases with Microscopic Examination of Portions of Nerves Removed, and Report on Later Condition of Patients.—By W. W. Keen and W. G. Spiller.

Method of Total Extirpation of Gasserian Ganglion for Trigeminal Neuralgia, by a Route through the Temporal Fossa and beneath the Middle Meningeal Artery.—By Harvey Cushing.

Method of Exposing Gasserian Ganglion; Removal of Superior Maxillary Nerve.—By Gwilym G. Davis.

Medical Ethics and Medical Journals.—By P. Maxwell Foshay.

Philadelphia Medical Journal, April 28, 1900.

Exophthalmic Goitre; its Complications and Affinities.—Roberts Bartholow says that the most useful single remedy for this affection is galvano-faradism, the descending stabile current being applied so as to include the pneumogastric and cervical sympathetic nerves within the circuit. In the cases in which cardiac symptoms predominate sparteine sulphate and picrotoxin, combined perhaps with the sulphates of iron and manganese, are of value. In the more chronic cases, associated with valvular lesions, fibroid degeneration of the thyroid, and pigmentation of the skin, he has had the best results from a solution of sodium iodide ʒ v., sodium bromide ʒ iii., sodium arsenate gr. i., in distilled water ℥ iv., in teaspoonful doses three times a day.

An Early Sign of Tuberculosis.—Thomas F. Harrington calls attention to a widely dilated condition of both pupils as symptomatic of very early tuberculous infection. He says that he has time and again observed dilated pupils in patients with other diseases or in apparent health, and has so frequently seen tuberculosis occur at a later day that he has come to associate this sign with incipient tuberculosis.

Boston Medical and Surgical Journal, April 26, 1900.

Splenic Pseudoleukæmia.—R. C. Cabot says that in the diagnosis of this disease we have to distinguish (1) cases of idiopathic splenic enlargement without any anæmia or any other symptoms, which are not very uncommon. (2) We must exclude pernicious anæmia, in which a slight enlargement of the spleen is almost always present, and sometimes a very considerable one. (3) We must distinguish the disease from cirrhosis of the liver, which is often extremely difficult. (4) Splenic tumor associated with chronic malarial poisoning must also be excluded. (5) From leukæmia the disease may be easily and quickly distinguished by the blood examination. (6) The anæmias of children are frequently associated with enlargement of the spleen, with or without leucocytosis, and their classification is still unsatisfactory. As a rule such cases are usually considered secondary to rickets or syphilis. As to the prognosis, some of Osler's cases have lasted twelve years, and the patients are still in good health. Splenectomy was done in one of his cases with favorable results. The author considers it a reasonable method of treatment, as splenic enlargement seems to have preceded the anæmia in all the recorded cases in which the question has been looked up thoroughly.

Splenic Anæmia.—James Marsh Jackson reports the case of a woman twenty-eight years of age. At the physical examination a mass was found on the left side extending from the seventh rib diagonally across to the umbilicus, and then toward the right anterior spine; dulness extended over into the left flank, and back and down to the crest of the iliac bone on the left side. The mass descended slightly with inspiration; edge (right), notched twice; otherwise the mass was perfectly smooth. The rest of the abdomen was soft, tympanitic, and not tender. The examination of the blood showed: red cells, 4,076,000; white cells, 5,200; differential count, 500 cells; polymorphonuclear neutrophiles, 36.2 per cent.; lymphocytes, 58.7 per cent.; myelocytes, 4.5 per cent.; eosinophiles, 0.6 per cent.

Splenic Anæmia.—John Lovett Morse reports two cases. Anæmia of various grades of severity, with enlargement of the spleen, with or without leucocytosis, is not at all uncommon in infancy. It is especially common in rickets. The splenic tumor and anæmia seem independent of each other, and are both probably the results of some common cause, which in infancy is apparently always some profound, complicated, and obscure disturbance of the nutrition. Reasoning from analogy the author is inclined to think that these unusual cases of anæmia and splenic enlargement in adult life may be due to obscure disturbances of nutrition, and may also be independent of each other and the results of a common cause.

Splenic Anæmia.—Henry Jackson reports a case in a young man aged twenty years. The physical examination showed splenic dulness from the eighth rib to just below the costal margin, where the edge was plainly felt, smooth and rather hard. Red cells, 4,000,000; hæmoglobin, twenty per cent.; polymorphonuclear neutrophiles, sixty-one per cent.; lymphocytes, twenty-nine per cent.; large mononuclear and transitional forms, eight per cent.; eosinophiles, two per cent. He suffered greatly from bleeding hemorrhoids. At the present time he is not anæmic, but the spleen remains enlarged. The diagnosis is obscure, but it was probably a case of splenic anæmia.

Medical News, April 28, 1900.

Interesting Case of Syphilis. Epithelioma.—In the first of these two cases reported by L. Blake Baldwin, the condition of the patient before treatment was appalling, the entire body being covered with ulcerating lesions, two hundred and eighty-four in all, and the weight having fallen from one hundred and seventy-eight pounds to ninety pounds in fourteen weeks. The stomach resisted five-grain doses of potassium iodide, and he was treated with wet bichloride-of-mercury dressings applied to all ulcerated surfaces except the cranium. After the first week the wet dressing was applied to the head also. Internally he was given the pure juice of five pounds of beef daily, seasoned with salt and pepper, which amount was increased during the first week to eight pounds. He was also given gr. xl. of potassium iodide three times daily, the dose being increased during the first week to gr. cxv. t.i.d. Following the removal of the crusts and cessation of the suppurative process, the ulcers were dressed with Unna's emplastrum hydrargyri mull. His recovery was rapid: on the fourteenth day he walked unassisted to meals, and two months after the first consultation he weighed one hundred and eighty-seven pounds. The second case reported was one of epithelioma of the face in a Polish woman, together with eruptions on the abdomen, breast, and thigh. The original eruption on the face began eleven years ago as a black pimple with but little discharge. The patient had borne fifteen children. There was no history of sore throat or falling of the hair, nor any necrotic ulceration.

Cancer of the Breast and the Results of Operation.—Clarence A. McWilliams studies the statistics of one hundred cases, and presents the following summary: Trauma present in 44.6 per cent.; married, 74 per cent.; children born to 66.6 per cent.; average number of children to each, 5; pain present in 56.2 per cent.; nipple retracted in 45.2 per cent.; right breast involved in 51; left breast involved in 49; axillary glands palpable in 48.9 per cent.; axillary glands found cancerous by microscope, 78.6 per cent. Average age was forty-nine years six months twenty-six days. Mortality of operation, four per cent. Average length of time in hospital, twenty days. Prolongation of life for one year, fifty-nine per cent.; for two years, thirty-six per cent. Cured (no recurrence at end of three years), thirty-four per cent. Recurrence took place in one year in twenty-one cases; in two years in twenty-eight cases; locally in fifteen cases; in lung in six cases. Average length of time in recurrent cases from operation to death, one year two months twenty days; average length of time from period of recurrence to death, five months.

Cancer Occurring in Acid Parts of the Body.—A. L. Benedict presents statistics tending to show that the great majority of cancers develop in acid media. Whether acid parts of the body happen to be where mechanical traumatisms are frequent, or whether the localization is due to some unsuggested cause, the writer does not pretend to state.

Some of the Reasons why the Surgical Treatment of Nasal Disease has been Placed on a Conservative Basis.—By Clarence C. Rice.

After-Treatment of Tenotomy of the Eye Muscles.—By Alexander Duane.

A New Traction Hip-Splint.—By L. Blake Baldwin.

New York Medical Journal, April 28, 1900.

The Relation of Hydrochloric-Acid Secretion to Indicanuria.—According to A. A. Jones, indican bears no constant relationship to the secretion of hydrochloric acid in the stomach. The later portion of the article discusses the matter of indican in its general relation to various diseases. It now seems settled that this substance is the product of putrefaction of albuminous matter caused by bacterial action. It is produced when pus formation, gangrene, necrosis, or ulceration takes place. The mother-substance is indol. It is always present in the bowel excepting in the sterile gut of the new-born. An excessive amount of indican is present in ileus and in gastric ulcer.

Ethylic Bromide (C_2H_5Br) Anæsthesia Preliminary to the Use of Sulphuric Ether.—G. R. Fowler commends the following plan: From one to two drachms of ethylic bromide is placed upon the inhaler, and in from thirty to forty-five seconds, according to the freedom with which the patient breathes, the administration of the sulphuric ether is begun, without changing the inhaler, and proceeded with as in ordinary ether anæsthetization.

A Contribution to the Histo-Pathology of Epidermolysis Bullosa (Hereditaria).—By G. T. Elliot.

Nitrous Oxide; Ether; Chloroform.—By S. Ormond Goldan.

The Diagnosis of Hysteria.—By C. W. Burr.

The Lancet, April 21, 1900.

Coxa Vara.—C. B. Keetley defines this affection as a deformity of the upper epiphyseal region of the femur in which the head of the bone sinks to a lower level than normal, in extreme cases almost touching the lesser trochanter. The upper border of the neck of the femur is longer and the lower border shorter than normal; hence the neck is more horizontal than normal, or it may descend instead of ascending in the usual way. The articular surface of the head may thus come to look downward. The neck is also bent in a horizontal as well as in a perpendicular plane, with the convexity forward. The underlying condition is rachitis of adolescents. The author was the first to recognize the nature of the deformity, and reported a case in the *Illustrated Medical News* of September 29, 1888. Since then Ernst Müller and Kocher have described the affection at great length.

Note on the Influence of the Temperature of Liquid Air on Bacteria.—Allan Macfadyan and S. Rowland report the results of exposing various micro-organisms (bacillus typhosus, bacillus coli communis, bacillus diphtheriæ, bacillus proteus vulgaris, bacillus acidi lactici, bacillus anthracis, spirillum choleræ asiaticæ, staphylococcus pyogenes aureus, bacillus phosphorescens, a sarcina, a saccharomyces, and the bacteria in unsterilized milk) to the temperature of liquid air (— 190° C.) for a period of some days. In no instance could the slightest structural alteration in the bacteria be discovered, nor could any impairment in the vitality of the organisms be detected, except that in one or two instances the growth in the sub-cultures was slightly delayed.

The Production of Local Anæsthesia in the Ear.—Albert A. Gray comments upon the difficulty of inducing anæsthesia of the unperforated drum membrane with aqueous solution of cocaine or eucaine, due to the fact that the nerves terminate in the inner layer of the tympanic membrane, and the drug must be made to penetrate the epithelial and dense fibrous layers before it comes in contact with the nerve termination. The author has overcome this difficulty by employing a solution of five parts of cocaine hydrochlorate in fifty parts each of dilute alcohol and anilin oil. He finds that a few drops of this solution instilled into the meatus and allowed to run down on to the tympanic membrane will quickly induce complete anæsthesia of this part. Several cases of the successful employment of this solution are reported.

On Backache as a Symptom of Rectal Disorder.—E. Harding Freeland calls attention to the frequency with which the presence of backache points to disease of the rectum, and says that when it is associated with symptoms referable to the other pelvic organs, the bladder or the uterus, the rectum will not infrequently be found to be the organ primarily at fault. He reports several cases in support of this view. As the earliest sign of incipient cancer of the rectum he thinks it is of especial value.

On the Causation of Nervous Symptoms in Typhoid Fever, with an Experimental Study of the Action of Typhoid Toxins on the Ganglion Cells of the Central Nervous System.—By Alexander G. R. Foulerton.

Epileptic Attacks Preceded by Subjective Auditory and Taste Sensations, Probably due to a Tumor of the Left Temporo-Sphenoidal Lobe.—By J. Mitchell Clarke.

Dislocation of the Epiphysis of a Metacarpal Bone.—By E. Kerr Herring.

The Medical Press and Circular, April 11, 1900.

Complicated Case of Double Ovariotomy in a Girl.—J. Halliday Croom relates a case in which there had been a swelling of sixteen months' duration in a girl of eighteen who had never menstruated. Everything pointed to cancer except the age. Blood-stained fluid was removed from the pleural cavity, as well as from the abdomen. A dermoid tumor was removed, the ovary on the opposite side being found healthy. Two years later the patient came again under observation for a swelling of six weeks' duration, and a large hard tumor was found along the middle line with dulness almost continuous with that of the liver. A cystic papilloma, probably starting from the other ovary, was removed.

A Case Simulating a Perforating Gastric Ulcer.—J. W. Thompson and Conway Dyer relate an instance in which the symptoms pointed to ulcer of the stomach. The abdomen was opened and a coil of jejunum was found intensely congested with two gangrenous spots. Resection was done with the Murphy button, and the bowel was flushed with sterile salt solution. The bowels moved on the fifth day, and the button passed on the eighteenth day. Prompt operation in such cases may save life.

A Case of Rupture of the Quadriceps Tendon.—Arthur H. Burgess relates the steps of an operation for injury above the knee with loss of power of extension. The tendon was drawn down and sutured to the patella by three stout silk sutures. The course was satisfactory, the sutures being removed on the twelfth day. Five weeks later the patient walked without support. Non-operative treatment is not likely to yield a good result.

Practical Observations on Cancer of the Breast.—By Sir William M. Banks. (Lettsomian lectures.)

A Case of Removal of Appendix Cæci.—By P. G. Lodge.

On Obstructive Dysmenorrhœa.—By Alexander Duke.

British Medical Journal, April 21, 1900.

Lengthening of Hamstrings by Operation for Contracture after Burn.—W. F. Brook reports this case in which the biceps tendon was split for three inches near its insertion, divided, and sutured. The inner hamstrings were divided transversely at different levels three inches apart. The proximal end of the semitendinosus, which had been cut at the lower level, was sutured to the distal end of the semi-membranosus, which had been cut at the higher level. The other ends were shunted into their neighbors and sutured. The boy was admitted to the hospital in February, 1899. In February, 1900, he walked without a limp and without the slightest effort.

Calculi Impacted in the Ureters.—David Newman writes of the pathology, symptoms, and surgical treatment of this subject. The calculus may be impacted in one ureter, the other kidney being competent, or the calculus may be impacted in one ureter, the other kidney being incompetent. The symptoms depend upon whether the morbid processes involve one or both kidneys. The blocking of the ureter is generally preceded by renal colic coincident with blood in the urine. The operative procedure depends upon the position of the stone.

Large Sarcomatous Neuroma of the Internal Popliteal Nerve.—George Buchanan recounts the occurrence of a large sarcomatous tumor of the trunk of the internal popliteal nerve following a blow on the leg. The leg had finally to be amputated. The tumor was a round-cell sarcoma. This case showed that nerves may be extensively infiltrated and disassociated with comparatively little degeneration resulting.

Five Cases of Complete Forward Dislocation of the Knee-Joint Occurring Simultaneously.— Ernest V. Eames reports these five cases, the result of an accident at the Shipley collieries, Derbyshire. All but one patient recovered. They all feel "a change in the weather" in the injured member.

Sclerema Neonatorum.—By John William Taylor.

Münchener medicinische Wochenschrift, April 10, 1900.

The Catgut Question.—Carl Lauenstein believes that the question has come to the point of definite solution, since during the past twenty years a whole series of methods of preparation have come up for securing a germ-free article. If infection occurs, it must be secondary, from the hands, air, skin, or mucous membranes. Attention must be paid to the best methods of using the catgut suture. Aseptic catgut should be further subjected to antiseptic processes. The possibility of making it germ-free, added to the advantages of its being absorbed, make catgut the best suture and ligature material. It will be surpassed only by some material having equally good qualities, while not swelling up in the tissues nor offering a favorable medium for bacterial growth. Various methods of sterilization are given.

Periosteal Transplantation of Tendons in Paralysis.—Fritz Lange says that orthopædics is no longer a trade, but a science. It must be wrested from the bandage makers, manipulators, etc., just as surgery a few years ago was taken from the hands of the barbers. He presents numerous illustrations and diagrams to show how transplantation of muscle directly to the periosteum acts better than when active muscle is attached to the tendons of paralyzed muscle.

The Treatment of Pes Valgus.—A. Hoffa presents an illustrated article, a new method of treatment for pes valgus, which, in recent years, has been distinctly separated from ordinary flat-foot. He thinks that by shortening the tendon of the tibialis posticus a decided advance in the treatment of the affection will be made.

Bacteriology of the Mechanico-Chemical Disinfection of the Hands.—By Ferdinand Schenk and Gustav Zaufal.

The Determination of the True Size of Objects by Means of the Roentgen Process.—By Professor Moritz.

On Restricting the Antiseptic Operative Field.—By G. Walcher.

A Pocket Sterilizing Apparatus.— By Dr. Bofinger. (Illustrated.)

Surgical Suture and Ligature Material.—By H. Braun.

Asepsis Contra Antisepsis.—By Otto Lanz.

French Journals.

Rheumatic and Neuropathic States.—Maurice Faure treats of conditions secondary to the grippe with persistent infections of the naso-pharynx. He concludes that these infections may persist for a long time, being accompanied by fever, malaise, intense fatigue, night sweats, insomnia, and loss of flesh. Articular and nervous affections may be due to toxins secreted in the infected cavities. These manifestations disappear rapidly under the influence of orrhotherapy in weak repeated doses.—*La Médecine Moderne*, April 11, 1900.

The Rôle of Engorgements of the Liver in the Predisposition to Pulmonary Phthisis and Secondarily in its Course.—Dr. Guerder gives thirteen observations, and discusses the causes, symptoms, nature, pathogeny, and treatment. The latter consists in the application of revulsives over the liver region, in intestinal antisepsis, regimen, and rules of hygiene, all of which are dilated upon.—*Revue de Thérapeutique Médico-Chirurgicale*, April 15, 1900.

Acute Dermatomyositis.—L. M. Bonnet speaks of this severe disease, which may prove fatal within a few weeks or months. The history, etiology, symptoms, forms, course, diagnosis, pathology, pathogeny, and treatment are given, together with a full bibliography. The only treatment is symptomatic, directed to the pain. Internal remedies seem useless.—*Gazette des Hôpitaux*, April 14, 1900.

Concerning Some Renal Accidents Observed in the Course of Acquired Syphilis.—Gabriel Delamare discusses the nature and frequency of renal complications of syphilis, and whether malaria may be, in such instances as he brings forward, the underlying cause and syphilis the determining factor.—*Gazette des Hôpitaux*, April 12, 1900.

Polymorphous Dermatitis.—L. Brocq presents with colored pictures a case of painful pruriginous circumscribed polymorphous dermatitis, and discusses its relationship to Duhring's disease. Successful means of treatment have not yet been found.—*La Presse Médicale*, April 14, 1900.

The Journal of Tropical Medicine, April, 1900.

Ticks and Tick Fevers.—L. W. Sambon describes the life history of ticks, and the diseases caused by the several varieties, such as redwater fever, louping ill, the disease of Miana, the disease of Tete, and various diseases of Central and South America. Few measures suggested for the destruction of ticks are adequate or practicable. A valuable remedy for immediate use is the powder of the pyrethrum flower, which should be dusted between the sheets of the bed. When a tick has fixed itself on the skin, the only indication is to induce the voluntary detachment of the animal by the application of a drop of olive oil, turpentine, benzene, or petroleum on the parasite, rubbing its ventral surface with a feather or spill of paper dipped in oil. Forcible detachment gives great pain, and the rostrum remains embedded in the skin.

The Endemic Centres of Plague.—In a second article on this subject, Frank G. Clemow reviews the history of the hill plague of India. The relation of the centres of plague in the Himalayas to the epidemic which has raged in India since 1896 has been the subject of much discussion. Either the disease developed spontaneously in Bombay, or it was imported from elsewhere. Some published facts seem to point to a possible importation of the plague to Bombay from its endemic home in the Himalayas. The only other alternative suggestions are that it came either from Central Asia or from Mesopotamia or Persia. The author considers each of these possible sources of infection in turn.

Peculiar Condition of the Hair.—R. C. Bennett, of Trinidad, describes a peculiar condition of the hair in a negro child, illustrating his description with photographs. The hair grows luxuriantly and separates itself into thin rope-like strands, made up of closely interwoven meshes. The strands measure from six to twelve inches in length. The parts nearest the skull are black; the distal ends are a pronounced red, due to exposure to the sun. The condition is congenital. There is much superstition among the natives affected, and children are obliged to carry this abnormal mass until they are old enough to cut it away with their own hands. After cutting, the condition does not recur.

Upon the Part Played by Mosquitos in the Propagation of Malaria.—By George H. F. Nuttall.

A Sketch of the Leper Asylums, British Guiana.—By F. A. Neal.

American Journal of the Medical Sciences, May, 1900.

Senile Bronchitis.—Reynold Webb Wilcox discusses the bronchitis of the aged and the best measures for its amelioration. He condemns the employment of opium or any of its alkaloids, which, he says, leads simply to an accumulation of secretion in the lungs, killing the patient by asphyxia, or more gradually by a septicæmia, resulting from gradual absorption of putrid material. The best remedies are strychnine and ammonium carbonate. When the expectoration is markedly purulent and foul, much good may be effected by the administration of creosote carbonate in twenty-drop doses in sherry every four hours. The inability to exercise, existing in many cases, may be compensated for in a measure by massage. Finally the greatest care must be taken to improve the patient's general health by regulation of the diet, attention to the skin, the ordering of suitable clothing, etc.

An Analysis of Fifty-One Cases of Pneumothorax.—John Lovett Morse says that from seventy to eighty-five per cent. of all cases of this affection are tuberculous in their origin. The prognosis of traumatic pneumothorax is good, and that of the condition when secondary to abscess of the lung is fair. Tuberculous pneumothorax is twice as frequent on the left side as on the right. Its onset is usually rather acute, sudden pain and dyspnœa being the most common initial symptoms. Recovery occurs in about fifteen per cent. of all cases, but these generally terminate in death from pulmonary tuberculosis later. The pneumothorax is usually complicated by the presence of fluid, but it may be simple. Fluid is almost always present in cases lasting longer than a week, and it is more often purulent than serous.

The Acute Pneumonic Form of Tuberculosis.—Arthur W. Elting reports a case of this nature, and sums up the main clinical features of the disease as follows: The onset is often without a definite chill. The fever at first is regular, irregular, or remittent, and is practically always of a remittent character in the later stages. Marked dyspnœa and cyanosis are usually absent. The consolidation is of variable extent. There is pain in the side, with cough and a sputum, which is at first typically pneumonic, but in a week or ten days may assume a greenish tinge, and will then be found to contain tubercle bacilli. The leucocytosis usually associated with acute lobar pneumonia is absent, in some cases at least, in acute tuberculous pneumonia.

The Differential Diagnosis of Ectopic Gestation.—Edward P. Davis reports three cases illustrative of the difficulty of diagnosis in many of those cases. He says that shock referred to the abdomen occurring in woman capable of pregnancy should invariably cause a suspicion of ectopic gestation, and if the shock is pronounced, the abdomen should be opened and any abnormal conditions there found should be promptly treated.

A Critical Summary of the Literature on the Surgery of the Stomach.—By Charles H. Frazier.

A Case of Multiple Neuro-Fibromata of the Ulnar Nerve.—By W. W. Keen and William G. Spiller.

Two Cases of Tabes Dorsalis in Negroes—Husband and Wife.—By Albert Phillip Francine.

The Clinical Aspect of Plague.—By Frank G. Clemow.

Zeitsch. f. diätet. und physik. Ther., vol. iv., No. 1, 1900.

Therapeutic Use of Vegetable Diet.—Th. Rumpf reports his experiments with a subject fed on a vegetable diet. Some vegetarians take vegetables pure and simple; others add milk, cheese, and butter to their diet. All animal food is excluded. Vegetable diet has certain dangers, namely, an underfeeding, and in women often a chlorosis with marked weakness. The advantages of a vegetable diet lie in the fact that overfeeding, especially with proteids, is avoided, that the intestinal function is increased, and that large and free movements occur. The number of pulse beats per minute is lessened with vegetable diet. In one case Barlow's disease and in another a severe rickets followed the prolonged use of Lohmann's vegetable milk. In cardiac weakness a pure vegetable diet is contraindicated. Vegetable diet is most useful in chronic constipation.

Should Physicians Suffering from Pulmonary Diseases Seek Ship Service?—Emanuel Freund relates his observations as based upon a two years' experience. During the first five months the catarrhal symptoms, bad breathing, and cough disappeared. The winter storms caused exacerbations of the old catarrh. In all, a two-years' sea-voyage produced (1) a marked increase of the bronchial catarrh, (2) a weakness of the digestive apparatus, (3) a loss of body weight amounting to twelve pounds.

The Newer Methods of Treating Lupus.—O. Lassar discusses at length, with eighteen photographs, the methods of cauterization by superheated steam, phototherapy, and radiotherapy. All three have improved numerous inoperable lupus cases.

The Osmotic Pressure of the Secretions in their Relation to the Occurrence and Amelioration of Disease Processes.—By Alexander Poehl.

Nourishment of Prisoners.—By Felix Hirschfeld.

Zeit. für klinische Med., vol. xxxix., Nos. 5 and 6, 1900.

Pathogenesis of Eclampsia.—W. Stroganoff concludes that eclampsia is an acute infectious disease, caused by a volatile contagium which usually enters the system of the woman by way of the lungs. The causative agent possesses a weak degree of virulence, and in some women finds toward the end of pregnancy, during parturition, and in the early days of the puerperium favorable conditions for its development. The same may be conveyed to the fœtus and attacks boys and girls indifferently. The contagious element of the disease possesses great resistance and retains its virulence for about three weeks. The incubation of the disease is most generally from three to twenty hours. Being an infectious disease of a contagious nature, it occurs mostly in lying-in institutions and attacks healthy women. Primiparæ, twin cases, and nephritic subjects are particularly predisposed. Cases must be isolated and the rooms and attendants disinfected.

Experiments upon the Metabolic Processes in a Diabetic Patient, with Special Reference to the Sugar Formation out of Proteids and Fat.—Hugo Lüthe concludes that certain forms of proteids, namely, animal tissues, when given to diabetic subjects are not indifferent as to the elimination of sugar; indeed, after the use of a casein and pancreas diet the sugar elimination is greater than that following the ingestion of roast beef and the calf thymus. The sugar excretion is greatest after the use of roast beef. If but little proteids and no carbohydrates are used for food, then a great amount of fats must be oxidized. Daily observations and analytical tables accompany the article.

The Blood Pressure in Healthy Persons.—S. Jellinek concludes that (1) normal blood pressure varies within very wide limits, 80 mm. Hg. being the minimum and 185 mm. Hg. the maximum; (2) that in many instances the blood pressure of the right hand is greater (one-quarter) than the left; (3) external irritations and influences—baths, marches, shooting, etc.—do not show any fixed effect upon the blood pressure. In some there is increase, in others decrease of blood pressure, while in others again there is no visible change. (4) No relation could be ascertained between blood pressure and pulse count.

Leucopenic Anæmia.—A. v. Decastello and Ludwig Hofbauer say that in all cases of anæmia uncomplicated with glandular involvement, there is an increase in the percentage of lymphocytes and correspondingly a diminution in the quantity of the multinuclear neutrophile elements. Leucopenic anæmias associated with glandular disease (spleen, lymphatic glands) show a varying quantity as to the relative percentage between the multinuclear and uninuclear elements. Numerous cases of different anæmias without apparent changes in the lymphatic apparatus are tabulated.

Experimental and Clinical Tests with the Riva-Rocci Sphygmomanometer.—Gumprecht mentions the advantages of this instrument over others such as Hürthle's, Mosso's, Gaertner's, and Basch's. The idea of the instrument is based upon the obliteration of the pulse by means of a measured pressure. Its use with experimental and clinical observations at all ages, both in health and disease, is given at length with charts, diagrams, and illustrations.

Sensory Crises in Tabes Dorsalis.—F. Umber states that while gastric, enteric, laryngeal, vesical, cardiac, testicular, and ophthalmic crises have been occasionally reported, the disturbances in the course of sensory nerves, such as those of smell and taste, are little known and seldom observed. The full history of a case in point is given.

Pentosuria.—Manfred Bial describes two instances of chronic pentosuria occurring in his practice; only two other cases have thus far been reported. Unlike glucose there is no fermentation and no polarization to the right. Other tests and reactions are formulated.

Gonorrhœal Peritonitis.—By Metzner.

Archives Générales de Médecine, April, 1900.

Pathological Thirst in General and the Thirst of Bright's Disease in Particular.—M. Klippel distinguishes the following groups of pathological thirst: (1) Compensatory thirst, as, for example, in cholera or after hemorrhage; (2) necessary thirst from polyuria for the elimination of a substance such as sugar, or urea, or chlorides, found in excess in the blood; (3) the dyscrasic thirst from alteration of the blood; (4) the thirst of the nervous diseases. The thirst of Bright's disease is found three or four times in every ten cases of interstitial nephritis in the arteriosclerotic patient. There is a sensation of heat and dryness almost always present in the mouth and pharynx. The mouth is not healthy in appearance; the saliva is diminished. Thirst is more frequent in the arteriosclerotic with Bright's disease than in the patient suffering from parenchymatous nephritis, when the quantity of urine is much less. This variety should be classified under the dycrasic group.

Lesions of the Thyroid Gland in Tuberculosis.—H. Roger and M. Garnier conclude that in the thyroid gland, as in other parts of the organism, tuberculosis can cause lesions the most diverse, and at first sight the most unlike. On more careful examination, however, they are more simple than would appear at the first glance. There are, indeed, two kinds of lesions: the phenomena of degeneration caused by the bacillus or its toxins; the defensive reactions or processes of cicatrization wrought by the organism. The initial lesion is a cellular degeneration. If the bacilli are located at certain points of the thyroid the lesions of the cells will be followed by abundant diapedesis, and the leucocytes forming clusters about the colonies of microbes will give rise to tuberculous granulations. At the same time the diffusion of the toxin will cause in the rest of the gland diffuse or systematic sclerosis.

Curative Orrhotherapy of Traumatic Tetanus.—M. Loeper and R. Oppenheim state that the intracerebral injection in traumatic tetanus is not so successful as was first hoped. The statistics show it to be inferior to all other methods of treatment. This probably results from the dangers inherent to its method of introduction. Subcutaneous injection appears at present the most rational treatment for tetanus. The number and quantity of the injections should be proportional to the intensity of the process. The method will probably save a number of cases. Intravenous injection has been successfully tried.

Two Cases of Vertebral Ankylosis of Gonorrhœal Origin.—P. Lereboullet and H. Bernard believe that the history of these two cases proves that a true vertebral ankylosis can be caused by gonorrhœal rheumatism.

Practical Method of Direct Estimation of the Quantity of Hæmoglobin in the Blood.—By T. W. Tallquist.

Revue de Chirurgie, April 10, 1900.

Intra- and Peri-Hepatic Suppurations of Typhlo-Appendicular Origin.—Ed. Loison says that although the coexistence of appendicitis and of hepatic abscess is rare, still enough cases exist to show a causal relation between them. Microbes can be transmitted from the region of the appendix through the bile ducts, the hepatic artery, the portal vein, the lymphatics, and the peritoneum. Dieulafoy believes that in a closed appendix the colon bacillus acquires increased virulence and expansive force which enable it to migrate through the blood and lymph channels and invade distant organs. The author leans to the belief that impaired power on the part of the liver to destroy micro-organisms is the chief etiological factor in the production of the disease. True prophylaxis of hepatitis and peri-hepatitis will consist in removal of the appendix as soon as possible after the onset of appendicitis.

Advantages of Anterior Incision in Certain Cases of Resection of the Hip.—M. Rochet, comparing the advantages of anterior and posterior incision, concludes in favor of the former, as ankylosis in good position is more rapidly and easily obtained. Dressings are more easily applied, and with little disturbance of the patient, who can remain lying on the back during the process. The articulation has a relative firmness from the first dressing. The likelihood of secondary infection by inoculation of the wound is greatly diminished. The operation should, as a rule, be reserved for suppurating cases; still when there is painful osteo-arthritis, with night exacerbations and sensitiveness to the slightest movement or pressure, in spite of bandages and immobilizing apparatus, resection should be performed.

Epithelioma of Both Breasts.—A. Le Dentu and H. Morestin describe a case which occurred in a young woman aged twenty-seven years. There was an early stage of induration and tumefaction of both breasts, which came on very suddenly, each breast in two days' time becoming as large as the head of a child of six years. Acute mastitis was followed by a nodular stage, during which ascitic peritonitis developed; coincidently with the subsidence of the latter affection, the breasts became softened and smaller. In a fourth stage there was evidently a neoplasm of both breasts, but its course was long and torpid, in decided contrast with the precipitate onset. At the autopsy, the growth was found to be epithelioma.

Some Points in the Pathological Anatomy of Gastric Cancer.—B. Cunéo says that the extension of cancer of the stomach is distinguished by three peculiarities: early and extensive invasion of the submucous tissue, a tendency to extend toward the lesser curvature, and habitual integrity of the duodenum. Like all varieties of epithelioma, cancer of the stomach has a tendency to invade the lymphatic ganglia. Histological researches have shown that all the parastomachal glands should be extirpated, the endeavor being to remove them with the tumor. To extirpate the glands of the lesser curvature, this portion of the stomach will have to be resected as far as possible.

Scapulectomy, or Primary and Total Ablation of the Scapula, with Preservation of the Arm, in Cases of Malignant Tumors of the Bone.—By Lucien Picqué and Dartignes.

Uterine Fibroma with Multiple Pedicles.—By F. Terrier and E. Reymond.

Inoperable Cancer of the Vagina Treated with Local Applications of Methyl Blue.—H. R. Coston relates an instance of cancer of the uterus and vagina to within an inch of the vulvo-vaginal orifice, in which hemorrhage ceased and the condition improved under applications every second day of a three-per-cent. solution of methyl blue.—*Therapeutic Gazette*, April 15, 1900.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FIFTH TRIENNIAL SESSION.

Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day—Tuesday, May 1st.

The first session of the fifth meeting of the Congress of American Physicians and Surgeons was convened in the Lafayette Square Opera House at 2:45 P.M., with Professor Henry Bowditch, M.D., LL.D., D.Sc., in the chair, and William H. Carmalt, M.D., secretary.

After introductory remarks and announcements, the scientific business of the congress was taken up.

Adaptation of Pathogenic Bacteria to Different Species of Animals.—This paper was by Prof. Theobald Smith, of Boston. The doctor showed that medical science and medical art were concerned chiefly with the phenomena of human disease. All that medical science desired to know was the series of causes or antecedents leading to any given disease and the series of phenomena which unfolded itself within the body during disease. Medical art wished to know where human ingenuity might enter to modify, suppress, or eliminate portions of this series, so as to interfere with the progress of the disease and bring it to a standstill. By general consent hygiene devoted itself to the external phenomena; pathology, to the internal. A small proportion of the infectious diseases of man and a large proportion of the infectious diseases of higher animals were transmissible, or at least inoculable upon smaller animals, producing in them diseases having more or less constant characters. The range of infectiousness varied considerably and arbitrarily without any reasons at present assignable. The range of infective power seemed to a certain extent to coincide with the readiness with which the bacteria could be artificially cultivated on various substrata; or, in other words, with their degree of saprophytism. Thus the plague bacillus, the colon derivatives, the rabid septicæmia group, and anthrax, were quite readily cultivated, and their range was very wide. The investigation of infectious diseases of animal life had brought before us another phenomenon which was of considerable importance. Certain bacteria causing disease among different species had certain affinities which caused us to classify them together, and which enabled us, at the same time, to separate them clearly from other pathogenic groups. One of the most important of these groups consisted of derivatives of the colon bacillus, which produced epizoötics among swine, guinea-pigs and field mice, and spermophiles, which had been found associated with disease in horses, cattle, and certain birds. The tubercle bacillus furnished us still another illustration. The avian type has been recognized as a variety for some years. Similarly the tubercle bacillus of cattle had certain uniform characters which had thus far been found in culture from the human subject. There was one other question which was more or less associated with the subject, namely, the fluctuation of the virulence of pathogenic organisms and the bearing of this upon the appearance of infectious diseases in epidemic form. The commonly accepted view of the gradual self-limitation of epidemic diseases was the exhaustion of susceptible material. The recrudescence was similarly ascribed to the reappearance of a young, susceptible generation. Thus, the reappearance of the eastern plague after an interim of months was ascribed by one observer to the new generation of rats. If we indulged in a little speculation along teleological lines we should see that the attenuation of virus limited to one host was not an unreasonable hypothesis. We could assume that all parasitism tended toward a more or less harmless symbiosis. Dr. Smith was inclined to think that the great specific energy of many disease germs was acquired in early geological ages, possibly in animals of very different type from those now living. But it was not improbable that the process of making pathogenic bacteria was going on now in the animal world, if we noticed only that these bacteria had been transported by some accident from their unseen habitat to species which happened to be susceptible. In the South the micro-organism was practically a harmless symbiont of the blood. North of a certain line it produced a highly fatal disease in the same species, which endangered and might entirely interfere with the normal transmission of the blood parasite itself.

After the reading of Dr. Smith's paper, the president announced that opportunity for general discussion would be given after the reading of all the papers.

The Physiological Resources of the Body in its Defence against Bacteria and their Toxic Products.—Dr. Samuel J. Meltzer, of New York City, read this paper.

A Study of the Mechanism of Agglutination.—Prof. Harold C. Ernst, of Boston, presented this paper. He said that in the early observations upon the agglutinating properties of the serum of immune animals the facts in the case were developed with motile bacteria, as with Charrin and Rogers' (1889) studies with bacillus pyocyaneus in cultures in the serum of immune animals, and Pfeiffer's reaction in cholera, typhoid, etc., and it was notably the case now that the most definite reactions were obtained usually with motile bacteria. After reviewing the literature on the subject, he said that the relationship between the agglutinating property and the bactericidal property was indefinite from the point of view of immunity. The rat's serum, though extremely bactericidal, did not agglutinate at all. In the dog, also with a bactericidal serum, agglutination occurred very remarkably. Nor were the origin or chemical properties the same. The studies already made seemed to support the principle that the agglutinating property did not lie in and was in no way connected with the flagella of the bacteria concerned; that agglutination was not to be accepted as a specific property connected with a condition of immunity, although this was a difficult idea to give up; that a homologous nature of agglutination could be considered a positive characteristic, for how, then, could be explained the clumping of typhoid bacilli by diphtheria antitoxin? Finally, no universally applicable explanation of agglutination had yet been offered.

The Relation of Bacteriology to Clinical Medicine.—This paper was by Dr. Richard C. Cabot, of Boston. He said that bacteriology was in the closest relations with clinical medicine through the help it gave us in clinical diagnosis. Such assistance was given through the demonstration of the bacilli themselves in secretions or in the products of disease; through the agglutination test, and through the injection of soluble products of the growth of certain bacilli (tuberculin, mallein). So far only two, or possibly three, such bacteriological tests could be said to be in general use throughout this country, viz., the search for the tubercle bacillus in sputa, the search for the diphtheria bacillus in the throat, and possibly the agglutination test for typhoid. Other such aids to diagnosis, which seemed likely to come into more general use, were the examination of the blood, the sputa, the urine, the fæces, the cerebro-spinal fluid, the urethral, vaginal, and uterine secretions, the nasal, pharyngeal, and conjunctival secretions. Next to typhoid, Malta fever seemed at present the disease in the diagnosis of which we were most helped by the agglutination tests. To other diseases the diagnostic assistance of the agglutination reaction had not extended. Individual observers had reported success in the attempt to apply the serum tests to diagnosis of tuberculosis and croupous pneumonia, but their results had not been extensively confirmed. To a limited extent we were able to reverse the use of the agglutination tests. Instead of using the well-identified bacillus to test the body fluids of a doubtful case, we could use the body fluids of a well-identified case to test a doubtful bacillus. Of the diagnostic use of tuberculin, it was only necessary to say that, despite the warnings of Virchow, it had passed into general use, and deserved to be utilized much more widely still. The few who objected to its use were for the most part those who had not tried it. The use of mallein was well established. Statements regarding prognosis were apt to present an unrivalled material for the study of the art of hedging. Bacteriology was helping us to make our prognoses less meaningless. The clinicians had realized how difficult it was to interpret the results of bacteriological examinations; for example, how to draw the properly limited inference from the announcement of a positive Widal reaction, to be enough and not too much alarmed by a positive reaction to tuberculin, or by the finding of the Klebs-Loeffler bacilli in a patient's throat. Especially was this true when relatively indefinite quantitative expressions entered into the bacteriologist's report. Only he who made the test could really appreciate what was meant in a given case by such phrases as "very numerous tubercle bacilli, very virulent streptococci, very motile organisms, very numerous malarial organisms, etc." The municipal laboratory of the city of Boston now offered to examine for physicians material suspected as coming from any of the following diseases: Typhoid, tetanus, tuberculosis, rabies, diphtheria, malaria, glanders, influenza, pyogenic organisms, gonorrhœa.

Bacterio-Therapeutics with Especial Reference to Tuberculosis.—This paper was read by Dr. Edwin R. Baldwin, of Saranac. The speaker dealt with the various uses of bacteria and serums in the prevention and treatment of disease, with a more detailed account of those in tuberculosis. Living bacteria were little used except in vaccination for variola and anthrax. Dead cholera, plague, and typhoid bacilli were useful in prevention but irrational in treatment. Diphtheria and tetanus were as yet the only conspicuously antitoxic serums of practical value. Streptococcus, pneumococcus, cholera, typhoid, plague, and recurrent-fever serums were either bactericidal or bacteriological, and of greater value in immunization than in treatment. There were many extracts of tubercle bacilli under the general name of tuberculin, which the speaker enumerated and described. No permanent immunity was produced by any of them, though the new tuberculins had some immunizing power in animals. The method was not applicable to man, nor safe, because it was likely to produce chronic poisoning, even in healthy subjects. Research at present aimed to discover and utilize the mechanism of relative immunity produced by injections of bacillus substance. The nature of the tuberculin reaction was of importance. Of the various theories promulgated, that which assumed a ferment action, chiefly produced by secretions from leucocytes, was most in line with present knowledge. Many bacterial extracts, nucleins, and digestive albumoses excited the same reaction as tuberculin produced. Tuberculin used therapeutically had only a limited application, and as it did not immunize for any length of time, it might not be better than other substances that could produce local hyperæmia. The production of local hyperæmia was rational in lupus, tuberculosis, peritonitis, and, to a limited extent, in pulmonary tuberculosis. Serums were not yet successful as to antitoxic properties. They might be bacteriological or bactericidal. There was still hope for some efficient serum or extract of tissues, though possibly it might not be antitoxic.

The Etiology of Malarial Fevers.—PROF. WILLIAM S. THAYER, of Baltimore, read this paper. He was of the opinion that the disease was acquired through the gastro-intestinal tract, especially by drinking water; through inhaled air; by the bite of insects. The experiments of Celli, Marino, Zeri, Grassi, and Feletti were strong evidence against the idea that the disease might be acquired through the gastro-intestinal tract; while a careful study of the literature, as well set forth by Norton, revealed the utter lack of evidence in support of such an idea. With regard to the theory that the disease was acquired by inhaled air, it could only be said that while some general facts spoke in its favor, no positive evidence in its support had ever been adduced. That the disease might be acquired through the bites of insects, and especially of mosquitos, had become an attractive hypothesis. It then might be considered as proven that the malarial parasite possessed an extra-corporeal cycle of life, which was completed in the stomach wall of mosquitos of the genus Anopheles, and that members of the genus Anopheles were capable of transmitting malaria from infected to non-infected individuals. The doctor then reviewed the bites of insects indigenous to certain localities in relation to the pathological effects, and especially referred to the class of mosquitos which infected the suburbs of Baltimore.

The Bacteriology of Dysentery.—PROF. SIMON FLEXNER, of Philadelphia, read this very interesting paper. He said that there were few subjects in medicine that had attracted more attention than dysentery. Its history dated from the earliest written records, and its ravages, unlike those of many of the pestilential diseases, had continued perfectly unabated to the present day. The most ancient writing upon medicine—the Papyrus Ebers—contains allusions to dysentery; the oldest Indian medical writers referred to it under the name *atisar*, while Herodotus spoke of its prevalence in Thessaly. Hippocrates, however, was the first to regard dysentery as an independent disease. The speaker said that he should hesitate to bring before this audience a subject so time-worn, were it not for the fact that the nature and more especially the etiology of dysentery were among the problems which still awaited a satisfactory solution. The imperfection of our knowledge of the nature of dysentery was not due to lack of opportunity for, or of energy in, its study. The literature contained some of the most distinguished names among clinicians and investigators, thanks to whose efforts its clinical history, its epidemiology, and, to a less extent, its pathological anatomy had received partial elucidation. Nor had the disease, in the past quarter of a century, escaped the attention of the bacteriologists, although it must be confessed that the results of somewhat extensive studies along these lines had been far less conclusive than might have been predicted. Given a disease that was never entirely absent from temperate and tropical regions, that appeared with epidemic severity, that permitted of easy access to the materies morbi, one would certainly have been tempted to predict that the success achieved in so many other and apparently no less difficult fields would probably be repeated. That the attempt to establish a common etiological factor for all cases of dysentery had thus far failed, this audience need not be reminded. That this failure emphasized the existence of several pathological states for which the term dysentery was employed merely as the collective designation, need not be defended here. But that these conclusions regarding the disease might, after all, not be in keeping with the facts, was at least open to suspicion. When we recalled the protean nature of other infectious diseases, among the most common of which were tuberculosis and typhoid fever, there could be no *a priori* objection to the hypothesis that the causative agency of dysentery need not necessarily vary for each of the many types of the disease that had, from time to time, been distinguished. For the purpose of his inquiry he should consider briefly the clinical and pathological types. That the lines of demarcation between the several clinical and pathological types should be inaccurate was not a matter of wonder. Both the beginning and the end of any given instance might vary very widely, and the symptoms and lesions of cases arising sporadically in temperate climates might agree with those of dysentery occurring endemically in the tropics or epidemically in both localities. The terms "catarrhal," "tropical," "epidemic," and "diphtheritic" were far from signifying sharp-cut entities. The clinical manifestations and pathological lesions of the catarrhal variety occurred in all kinds of dysentery and in all places where the disease prevailed. Ever since the time of John Hunter there had been those who, upon pathological-anatomical grounds, had separated the endemic from the epidemic disease, and the line had been even more sharply drawn during the past decade, since the discovery of the amœba coli in its relations to tropical dysentery. But the distinction between tropical dysentery, which was characterized by ulceration and thickening of the intestines—especially the colon, the lesions beginning in the submucous coat of the gut—from the epidemic disease in which a false membrane existed, usually associated with ulceration without any primary involvement of the submucosa, was far from being sharp and constant. In this country diphtheritis had not been commonly observed in the ulcerative and amœbic form of dysentery, while in Egypt the two pathological conditions were not infrequently found together.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifteenth Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

EDWARD G. JANEWAY, M.D., OF NEW YORK, PRESIDENT.

First Day—Tuesday, May 1st.

The President's Address.—DR. EDWARD G. JANEWAY, of New York, in this address spoke of the advancement made in the last few years along the lines of pathology and chemistry, and in looking back had but one regret, *i.e.*, that of lost opportunities. He advised the younger members of the association to work assiduously for the advancement of true pathology and true chemistry.

An Experimental and Clinical Study of Acid Intoxication.—DR. C. A. HERTER, of New York, the author, being unavoidably absent, his paper was read by the secretary. Experimental evidence showed that calcium oxalate was precipitated on the addition of ninety-five-per-cent. alcohol. By this means one was able to separate it in the urine. In certain diseased conditions, such as melancholia, nervous fears, and indigestions, the amount of oxalic acid was markedly increased. On a diet free from oxalates, such as milk, no oxalates appeared in the urine, but on a mixed diet, as much as 67 mgm. of the oxalate might be excreted in twenty-four hours. Much of the experimentation had been done on dogs. When a dog was fed on a sugar diet no symptoms made their appearance until after about six weeks; then the dog had attacks of nausea and vomiting with interrupted diarrhœa, and organic acids and oxalates appeared in the urine. This went to show that the oxalates were formed in the body. The author raised the question of where the oxalates were formed in the body. He claimed that they were produced in the stomach of the dog by a ferment. In health there were no oxalates formed, but in certain morbid conditions in which there was a deficiency of hydrochloric acid. in the stomach, oxalates were formed there, probably by an organized ferment.

Dr. Tyson, of Philadelphia, said that if one examined the urine of certain individuals, apparently in perfect health, either during the day or night, one would find oxalate of calcium in the urine. He agreed with the author that a milk diet eliminated the oxalates from the urine.

Notes on Diabetes.—Dr. James B. Herrick, of Chicago, read this paper. He spoke of the occasional low specific gravity of the urine in diabetes, and said it was even lower than the normal. In one case cited, a man who had been drinking beer all the morning came into his office partially intoxicated and asked for a urinal. He passed 1,100 c.c. of urine having a specific gravity of 1.010. This specimen gave the usual reaction for sugar. Out of twenty-seven cases, twelve per cent. had had a specific gravity of 1.010 or less, and some as low as 1.004. Hence all urine should be tested for sugar, regardless of its specific gravity. Dr. Herrick also spoke of casts in the urine during diabetic coma. He said that polyuria was often associated with nephritis. In some cases he had found a trace of albumin, with a number of granular casts. Just preceding the attack of coma, casts became very numerous. Formerly this had been considered accidental. He had seen cases in which casts appeared in the urine twenty-four hours before coma came on; and he thought, therefore, their presence might forewarn one of the coming attack. The pathology was unknown, but he thought it probable that the condition was due to a toxico-chemical change taking place in the excreting cells in the kidneys at or around the loops of Henle.

The Relation of Uric-Acid Secretion to Epileptic Attacks.—Drs. James J. Putnam and F. Pfaff, of Boston, presented this communication, which was read by Dr. Putnam. After examining the urine excreted in twenty-four hours, and over a period of time including several seizures, he had come to the conclusion that there was no difference in the amount of uric acid excreted before or after the seizures.

Report of a Case of Acute Ascending Paralysis, Showing Hæmatoporphyrinuria.—Dr. Charles G. Stockton, of Buffalo, read this paper. It was the case of a young woman, a servant by occupation, who was hysterical and anæmic. Her urine was much darker than normal, and contained a trace of albumin. Sulphonal and salicylates failed to give relief. She was admitted to the Buffalo Hospital in September, and the physical examination showed a higher pitch at the left apex of the lungs. She had several areas of anæsthesia over the breast and buttocks, and she complained of weakness and loss of sensation in the legs. The urine was claret-colored, and remained so until the end. Her temperature was 100° F. Ophthalmoscopic examination showed optic neuritis. The patellar reflex responded slightly. She grew rapidly worse, and finally died. No autopsy was obtained. The claret-colored urine was examined most carefully. No xanthin or indican bodies were present. The color was not due to sulphonal, he said, for she had not taken it for two weeks. It was due to the pigment depending upon hæmatoporphyrinuria, which, as he thought, bore a direct relation to the inflammation of the spinal cord.

Dr. J. J. Putnam said he had had a similar case associated with multiple neuritis and progressive anæsthesia, with claret-colored urine. The patient lived thirteen days. The autopsy showed no change in the spinal cord.

Dr. E. G. Janeway said that the discussion reminded him of a lady who had been in the habit of taking trional, from gr. x. to gr. xx. every night for a year, to make her sleep. She was taken suddenly with nausea and vomiting and developed a mitral insufficiency and a general neuritis. She recovered.

The Relative Infrequency of Acute Transmissible Diseases during the First Year of Childhood, with a Discussion of the Probable Reasons for the Same.—Dr. A. C. Abbott, of Philadelphia, read this paper. He had some very interesting charts showing the percentage of death rates of children from the first to the tenth year, deaths being considered from measles, scarlatina, and diphtheria. The deaths from measles in children one year old were 27.4 per cent., and in those five years old 64.8 per cent. In children three months old the deaths from measles were 2.7 per cent., and in those of six months 7.7 per cent. He thought this could be explained without considering acquired immunity, and that it was due to the period of nursing. He thought that the mother conveyed something to the child through her milk which caused the child to become immune.

Dr. George B. Shattuck, of Boston, did not agree with the author as far as diphtheria was concerned. He thought that there was some other cause besides that of immunity from the mother's milk which kept a three-months-old child from having the disease.

Recurrent Vomiting in Children.—Dr. J. P. Crozer Griffith, of Philadelphia, read this paper. He reported four cases. The first one was a mild case of vomiting, lasting one day, and followed by recovery. The second case was more severe. The child had been sick four or five days and was obstinately constipated. On the fourth day the bowels moved, but this did not relieve the symptoms. Some bloody mucus escaped from the child's mouth, the patient being too weak to vomit. He had advised morphine hypodermically, and when the child seemed at the point of death the symptoms abated and the child recovered. The third case was similar, but an operation was performed for a supposed appendicitis, and the child died. The fourth case was complicated by nephritis, abdominal pains, sighing respirations, and slow pulse. It terminated fatally. Dr. Griffith said, in closing, that the exhaustion in these cases was excessive, so that the physician felt death was inevitable, but the change for the better came suddenly. The attacks lasted from one to ten days and occurred at irregular intervals. He thought that there was a tendency to outgrow the disease, and that it was probably due to some toxicity of the blood.

Dr. Stockton, of Buffalo, said that the vomited matter was pure gastric juice. He thought it occurred most frequently during the third and sixth month, and was a neurosis. He had never seen any deaths reported.

Dr. Johnson said he had had a case of coffee-ground vomiting, followed by rapid prostration, cyanosis, and cold extremities. The patient seemed to be just on the point of death when he began to improve. The condition seemed to be due to precocity of the child and an inherited neurasthenia, and not due to cold or tonsillitis. In the treatment, rest was of the first importance. He believed in hypodermics of water and the administration of food by rectum.

Sanitarium Treatment of Pulmonary Tuberculosis and its Results.—Dr. E. L. Trudeau, of Saranac

Lake, read this paper. In speaking of the so-called pre-tuberculous stage, he thought that the x-rays would give additional evidence, for a slight shadow might be seen corresponding to areas of consolidation. Tuberculin raised the temperature and made the diagnosis. He generally gave 1 mgm. as an initial dose. The treatment could be summed up in the words, rest, food, restoratives. It was customary to immobilize a tuberculous joint, and the same should be done with the lungs. Dr. Trudeau gave a number of statistics showing the results of sanatorium treatment. He had had twenty-three per cent. of cases apparently resulting in cure, but, he added, "Time was the only test of cure."

Dr. Bridges, of Los Angeles, said that he thought three-quarters of the cases of pulmonary consumption could best be treated outside of institutions.

Dr. Solis-Cohen, of Philadelphia, asked what Dr. Trudeau meant by rest, whether he meant rest of the lungs or of the body as a whole. In his experience exercise of the lungs was beneficial.

Dr. Trudeau closed the discussion. He said that if the temperature was 99°–99.5° F. once or twice during a week, and there were slight disturbances of health, this was enough to make him suspicious of the presence of tuberculosis.

Phlegmonous Gastritis, with Specimen.—This paper was read by Dr. Francis P. Kinnicutt, of New York.

Dr. William H. Welch, of Baltimore, recalled a similar case, in which death had resulted from peritonitis.

Dr. Janeway said he had had a case which had been diagnosed as perigastritis, general peritonitis being absent.

AMERICAN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

Surgery of the Stomach.—Dr. Robert F. Weir, of New York, introduced the general topic for discussion, viz., "The Surgery of the Stomach," by reading a paper on "Duodenal Perforation." (See page 749.)

Gastric Ulcer.—Dr. W. L. Rodman read a paper on gastric ulcer, non-perforating, with especial reference to hemorrhage. Passing over etiology, pathology, differential diagnosis, and prognosis, he spoke of the importance of intelligent medical treatment. From one-half to three-fourths of all cases resulted in cure thus in from four to five weeks. Kocher said that after five weeks there was danger, if the ulcerative process continued, of neoplastic change. Hence the speaker advised operation in cases which, after five weeks, refused to yield to treatment. He asked, should the ulcer be excised in cases in which hemorrhage was not prominent? It seemed doubtless the best treatment, because of neoplastic possibilities. The radical treatment was gaining in favor, but it must be conservatively used. The adhesions were of very great importance in determining whether partial gastrectomy or pylorectomy should be chosen. If they were very dense posteriorly, gastrectomy might be necessary. Gastro-enterostomy relieved hyperchlorhydria, and was of great value if shock was present, or if, when dense adhesions were present, the case could not stand partial gastrectomy. This was possible only in the absence of neoplasms. The indications for operation were: (1) Hemorrhage. The first time this occurred it must be treated medically. (2) If the patient was rallying from shock, operation should not be done, but venous infusion given. Only eight per cent. of cases resulted fatally from primary hemorrhage. (3) In a case in which there had been one free hemorrhage, with recovery, bleeding again two or three days later, operation seemed indicated. The speaker cited many cases to show that there should, at this time, be surgical intervention. Speaking of pylorectomy, he said it seemed the ideal operation when gastro-enterostomy was not necessitated by posterior adhesions, and when the neoplasm, if present, was localized and young. Gastro-enterostomy had a very useful future in multiple ulcer, and when the bleeding point could not be found. Excision of the ulcer was hopeful, and should be used unless adhesions were present. Ligation *en masse* promised well and should be practised by placing Lembert sutures on the outside as a first step. In closing, Dr. Rodman said that operation for acute hemorrhage was indicated with limitations, but for chronic hemorrhage the operative was the only course to pursue.

Perforating Ulcer of Stomach.—Dr. J. M. T. Finney, of Baltimore, discussed this subject. He spoke of the difficulty of adding anything new, and emphasized the importance of early diagnosis. The mortality of perforated cases was from 6.5 to eighteen per cent. in Johns Hopkins Hospital in cases treated medically. Since 1880, when Mikulicz first operated, two hundred and sixty-eight cases had been reported. There had been a rapid increase since 1896. The etiology was unknown, trauma and food being unimportant. Locality and sex were factors; it was more frequent in women (five cases) before the age of thirty years, than in men, in whom it occurs often after forty. He spoke of the importance of adhesions in protecting from subphrenic abscess, and of their influence in guiding pus, once formed, to remote quarters of the body. As to the site of the perforation, it was most frequently near the cardia, next at the pylorus, third, at the lesser curvature. The severity of the symptoms and the prognosis depended on: (1) the size of perforation; (2) whether, at the time of perforation, the stomach was empty or full; (3) the position of the patient (unimportant); (4) the nature of the infection, character and number of bacteria being of the utmost importance. Experiments with a case of duodenal fistula at Johns Hopkins Hospital showed that infected milk was discharged with the infectious organisms still active. Hence the speaker urged the necessity of using sterilized food, and of sterilizing the mouth for two days prior to operation. Hyperacidity seemed, under certain conditions, to favor development of germs. (5) As in typhoid, leucocytosis was of great importance when present. An important question was, Shall we use opium, and how much? The answer was, most emphatically, to use only as much opium as was absolutely necessary to ease the pain. Another question was, Shall we await shock? Equally emphatic was the answer, *i.e.*, to operate immediately. This was particularly true if the symptoms were growing more pronounced. Local anæsthesia, combined with a few whiffs of chloroform, if necessary, was of great importance in operating for diagnosis. Indeed, in this manner the entire operation was best done. The steps were as follows: the cardia should first be examined; second, the pylorus; third, the lesser curvature, and last, the posterior surface. He closed by speaking of the hopeful results of surgical intervention.

Malignant Diseases of the Stomach and Pylorus.—Dr. William J. Mayo, of Rochester, Minn., discussed this topic. He said that carcinoma was entirely a surgical disease, and emphasized the need of exploratory incision for early diagnosis. The curability of carcinoma depended largely on its histological structure: the greater the amount of stroma, the more favorable the post-operative prognosis. Colloid degeneration seemed very unfavorable, while the cylindrical-celled growth yielded the largest percentage of non-recurrence. The location was another factor in considering curability. The diagnosis at the cardia was easy, and the prognosis was bad, while the opposite was true at the pylorus. Lymphatic involvement, so called, was now known to be a simple septic glandular enlargement—the relation between the abdominal glands and the carcinoma being utterly different from that which existed between the breast and the axilla. Abdominal adenitis was, therefore, of little importance. The patient's condition was an indication of value, particularly if cachexia and ascites were present. These made the prognosis unfavorable. Every operation should be at first for diagnosis. The incision was median, and it was important that the pylorus should be freed enough to lift it from the wound. If necessary, the gastro-hepatic omentum should be cut. The conditions found might indicate a radical operation, palliation, or, the inadvisability of attempted relief. In the latter case, the wound should be closed by Halsted's method. Complete gastrectomy was the operation particularly for cancer of the body. We should be proud that this was first done by an American. Kocher's operation was preferable to Billroth's. The stomach should be cut away inch by inch and ligated as the operation proceeded. Suturing should be done in two stages. Czerny operated in two steps for extirpation, the operations being about three weeks apart. Curettage and cautery were not effectual. Gastro-enterostomy was the most useful of all gastric operations for palliative operation. Whether the suture or the Murphy button should be used depended on the operator. The peristaltic directions must be made to coincide. The speaker felt certain that the anterior portion of the stomach wall was the better to use in making the anastomosis, because of its easy access; for he did not agree with those who believed that the button might fall back into the stomach from the anterior wall, because of the formation of a funnel-shaped pouch which prevented it. Regurgitation of bile and vomiting were rare complications of this operation, and so rare as not to justify, at the preliminary operation, the introduction of a complicated technique, involving entero-anastomosis and other modifications.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day, Tuesday, May 1st.—Morning Session.

The meeting was called to order at 10 A.M., the president, Dr. George J. Engelmann, of Boston, in the chair.

Dr. Joseph Taber Johnson, of Washington, D. C., gave the address of welcome.

Cancer of the Vagina.—Dr. Pryor, of New York, read this paper. He reviewed the fact that cancer of the vagina was very rare. It usually involved the posterior wall of the vagina and extended underneath the rectum, then to the vaginal structures and to the uterus. He described the operation which he employed in two cases, giving as the first step a primary and preventive hæmostasis. By this not only the field of the operation was rendered dry, but migration of the cancerous cells was prevented. He avoided all injury to the cancerous field until hæmostasis was secured and the cancer had been charred by the cautery. He removed all the organs in which recurrence was apt to take place, and removed from above downward. He established an artificial anus near the site of the normal outlet of the rectum. The cancer was prone to spread by invasion of the tissues having a common source of blood. This operation sought the removal of all organs belonging to the vascular group in which the affected organ was placed. The speaker detailed the history of two cases operated on. The form of operation performed formerly was that of Olshausen, which was a blunt dissection of the vagina from the rectum. This was rather a failure. The steps in Dr. Pryor's operation were: (1) The general preparation of the patient; (2) the incision from the umbilicus to the pubes; (3) the ligation of the vessels and ligaments; (4) dissection of the bladder from the cervix and entrance to the vagina anteriorly; (5) removal of the vagina and the entire rectum; (6) ligation of the obturator artery to prevent anastomotic circulation being formed. The actual cautery was used for charring the cancerous mass. The vagina and rectum and the perirectal tissues were excised, and the formation of the artificial anus was established near its normal situation. The technique of the operation was illustrated by drawings, and the author emphasized the fact of the rarity of this form of malignant disease; he called special attention to the method of removing the rectum as high up as the sigmoid flexure, as well as almost the entire vagina.

Dr. Mundé considered it fortunate that these cases were rare. He had seen only two cases of primary cancer of the vagina in a long experience. He had curetted and cauterized. He did not consider that such bloody and radical work repaid for the slight benefit received by the patient, as recurrence was inevitable.

Dr. Sutton had seen but one case in thirty-four years, and had little faith in such radical operations. The pathology of cancer should engage our attention. Instead of a new method we needed to find the factor producing cancer.

Dr. E. Van de Warker felt that nothing had been gained by operation for cancer.

Dr. Montgomery said that the great frequency of recurrence of malignant disease, when it involved the vagina and extended into the parametrial tissue, and when it invaded the broad ligament, led him to believe questionable the operative treatment of these cases. It had been said that there was no plan of treatment by which a patient could be insured against relapse, and unfortunately we were unable even in the early development of the disease to say that it was not already carried into the parametrial tissue and beyond. He had frequently seen patients in whom he felt that an operative procedure would result favorably, in whom there was early return of the disease. He had seen other cases in which there was extensive destruction of the cervix, in which the question of the wisdom of an operation was a grave one, and yet in these patients several years had elapsed without recurrence. We were at present in a position of simple uncertainty; we could say in individual cases whether operation would afford a favorable opportunity for the recovery of the patient.

Dr. A. Lapthorn Smith said he had had little experience with cancer of the vagina, but considerable with cancer of the rectum. By removing the lower half of the rectum, drawing it down and removing all the glands that could be felt from below, he thought that he had removed all the disease, but the longest period that the patient lived was one year. Though little was gained in many cases, the uselessness of the operation ought not to be considered, but rather the number of women who were prevented by these adverse reports from being operated on; these being cases which possibly could have been cured.

Dr. Sutton said that in his experience the patients who were apparently in the best general health, but in whom there was a diseased blood condition, were almost universally the first to succumb to a return of the disease.

Dr. Byrne had had no experience with isolated cancer of the vagina. He was gratified to hear the gentlemen declare that there was absolutely no use in removing a cancerous uterus. This had been his feeling for many years, and he hoped that eventually the treatment which had been so successful in his hands might be given a fair and impartial trial.

Dr. T. A. Reamy would like to ask if the statements as made by these gentlemen meant that in no case was cancer of the uterus cured; or were the incurable cases confined to those in which the vagina and the lower portion of the uterus, the parametrial tissue, the lymphatic glands, and the region round about were involved?

Dr. Sutton replied that his remarks in a general way applied to all cancers in the vagina or uterus. He would make this reservation, that he had never seen a case of cancer of the uterus until it was well developed. As to seeing a case of cancer of the uterus when the epithelium was just beginning to break down, when it was almost impossible to make a diagnosis save by microscopical examination, he did not see one such case in a thousand.

Dr. E. Van de Warker said that he referred to simple epithelioma or cancer of the cervix, and to no particular stage.

Dr. T. A. Reamy must say that the gentleman was mistaken. It might be true that that was the history of the cases operated on and described by this distinguished man and his friend. We knew that these statements were not due to the fact that these gentlemen who had spoken in support of the statement were incompetent to do the operation thoroughly or successfully. He knew half a dozen women who had lived from six to ten years and two of them twenty years after having the cervix removed. The condition was proved to be cancer by the examination and report of the ablest pathologist and microscopists to whom he could have access.

Dr. George J. Engelmann thought that when it was said that cancer could not be cured, it was time to enter a protest. He granted that in a large percentage it could not be stayed; any man who would look at the diagram exhibiting the location and extent of the lymphatics would recognize that so soon as the disease had existed sufficiently long to involve the lymphatics to any considerable extent the disease was beyond the pale of operation, and in a large percentage no treatment would prolong the life of the patient. In order to tell how much benefit there was from cautery or knife in these excessive cases, it was only necessary to watch clinically the history of those left untouched, and it would be found that the patient lived longer when not disturbed; and therefore Dr. Engelmann spoke as radically as his friends. He had, however, seen cases in which the operation was done in time, in which the result was satisfactory. He had seen these results in the work of his friends, and had read the reports of other men all over the country of the same results, and therefore he protested again. In the earliest stage, the condition was primarily local.

Dr. Sutton said he had seen several cases of primary epitheliomatous growth of the vagina involving the rectum, and had had the opportunity to operate on two. It was reasonable to suppose that the growth would return much more quickly than it would in any other part of the body. Epitheliomatous growth, so far as his knowledge went, was much more rapid than scirrhous forms. If the operation advocated by Dr. Pryor did the most one could possibly do by ligating the vessels which led to the structures of the pelvis, and thereby retarded the disease, it seemed to him that it was a worthy operation. It might not be so radical as it seemed to be on paper. If we operated with the patient well exposed and in the Trendelenburg position, the vessels could be easily reached.

Dr. Pryor, in closing, said that possibly the next copy of the *Centralblatt für Gynäkologie* would tell us how to detect the cancer bacillus and point us to some antiseptic to apply to it; but up to that time we must be surgical. Cancer of the vagina and rectum must be viewed not as cancer of the vagina or of the rectum, but in the light of its complications. If the cancer could be operated for and a colostomy be done low down in the body, it provided a cloaca for retained fæces, and so seemed to him to be the operation of choice. As to the advisability of an operation apparently so severe as this, he took issue with Dr. Lapthorn Smith, and would not sacrifice the life of a woman with so grave a disease if his conscience indicated that she should be operated on, for fear some remote patient in the mountains might decline operation should the result be fatal. The operation was for cancer of the rectum and of the vagina, and was applicable to the graver forms of cancer in which the uterus may be involved.

Fecal Fistulæ.—Dr. I. S. Stone, of Washington, read a paper with this title. He said that one of the most distressing and annoying of post-operative sequelæ was fecal fistula. As was well known, the greater number closed spontaneously, yet it was occasionally found necessary to resort to some form of surgical relief. Perhaps the larger number of fistulæ followed in the wake of appendical abscess. It might be safely said that there was no routine treatment of fecal fistula. Mention was made of certain methods believed to be followed by the best results. A permanent fistula following an operation upon an appendical abscess might require anastomosis by exclusion. This operation had probably been the result of Dr. Senn's experimental work upon animals, and was especially required in fistula with a tortuous sinus not connecting with the intestine immediately under the external wound. In cases in which the cæcum and ascending colon were greatly thickened and firmly bound by adhesions, the surgeon might take a section of ileum as near the caput coli as convenient, and transplant it or make end-to-side anastomosis to the transverse colon. Reference was made to Dr. Kammerer's case, in which a very radical method was employed, and which the speaker described in detail; also to a suggestion by Greig Smith to cut down upon each side of the fistula (yet not through it) to the peritoneum without opening it, dissect about two inches of this away from the abdominal wall on each side or around the fistula as a centre, and then withdraw the peritoneum with attached and adherent bowel, far enough easily to close the fistula. Greig Smith took the position that peritoneal surfaces did not unite so firmly as though denuded, and claimed that these openings in the gut were closed safely and speedily by rough cicatricial coaptation. The pelvic surgeon frequently had to fear fistulæ resulting from uninjured bowel, which he encountered during enucleation of pus sacs, etc. These fistulæ were most difficult of closure, owing to their situation and to the fact that the function of the rectum served to perpetuate the fistula, since it was a receptacle or reservoir for gases and fecal matter. The speaker's successful experience with two cases of recto-abdominal fecal fistula of long standing was detailed, and the following conclusions were submitted: (1) that in all persistent fistulæ we must for obvious reasons remove any foreign body such as silk; (2) that all attempts at skin closure or by cauterization or curettage of persistent fecal fistulæ were generally successful. (3) In all cases in which a fistula connected with a superficial coil of intestine, the method of Greig Smith might be tried before resorting to radical operation. (4) In the deep-seated fistulæ requiring abdominal section choice must be made between excision and some form of anastomosis, for the case will rarely be found so simple as to permit inversion of the fistulous portion and direct suture. (5) In operating for such deep-seated fistulæ we must not fail to liberate imprisoned bowel and restore the normal peristalsis, permitting free motion of intestinal coils and directing the fecal current in its proper course. (6) Finally in recto-abdominal fistula, it should if possible be converted into a recto-vaginal fistula, and closure of the tract be secured before the temporary fistula was allowed to close.

Dr. Currier had seen but one case of fistula of the small intestine, and that remained obstinately open and the patient continued to lose ground. The patient was cured by section of the small intestine. In the cases including the small intestine nature could not be expected, according to ordinary anatomical and physiological conditions, to help much, and it was not therefore wise to wait. Radical operation involving portion of the bowel must be attempted as soon as possible. On the other hand, in the cases situated low down, and in which there was a discharge of fecal matter, he thought it was well not to be too hasty to institute operative procedures. He had seen a number of such cases in which by waiting nature had instituted a cure. Inasmuch as the applications which Dr. Stone had indicated were so varied and so severe, the speaker would advise giving nature a chance. This was a rule which he thought might well be laid down. He questioned whether the removal of silk or other foreign body in most cases would effect a cure. The silk, as a rule, was not applied to that portion of the bowel in which the fistula took place. He would say for himself that his general rule had been, when the condition seemed to be undergoing a rational process of development pointing to a cure, to wait and see if nature would not effect a cure, and not by attempting operative procedures possibly make the condition worse.

Dr. A. W. Johnstone said that, as a matter of justice to two dead men, he would state that the method outlined by Dr. Stone was taught by Lawson Tait to Greig Smith. The speaker assisted Mr. Tait the first time he closed a fistula in that way, which was his seventeenth operation. Ever since 1886 Dr. Johnstone had used that method in closing fistulæ of every description, and he succeeded on the third operation for closing ureteral fistula. He always used it on a vesicovaginal fistula, splitting the viscus and turning part of it in and part out. In ureteral fistula none but the very finest instruments could be used.

Dr. C. P. Noble said he had seen a goodly number of fecal fistulæ, and all had closed spontaneously except four. Three remained obstinately open; one recovered after operation. When the fistula was in the larger bowel and the case was not tuberculous, it was his experience that the prognosis was most excellent. In tuberculous cases the prognosis was very bad whether or not operation was done. In one such case operated on the result was a failure, and in quite a number the patients had died or the results had been unsatisfactory.

AMERICAN PEDIATRIC SOCIETY.

Twelfth Annual Meeting, at Washington, D. C., May 1, 2, and 3, 1900.

First Day—Tuesday, May 1st.

The Care and Treatment of Summer Diarrhœa.—The first session was called to order by the president, Henry Koplik, M.D., of New York, who gave an address upon "The Proper Care and Treatment of Summer Diarrhœa Cases." The speaker said in part, that he invited the society to a subject so broad and catholic that it could not fail to interest both physicians and laymen. The care of the poor children, whether sick or well, was assumed by the State in some instances, by private individuals in others. Improving the condition of these wards tended to our own betterment. The close housing of the poor during the colder months tended to the increase of accumulating filth and general dirt, to lack of fresh air for breathing, and to little personal cleanliness. If infectious diseases were not also increased the debilitated children were the more ready victims when they were exposed. In the summer the general health improved, but the tendency to intestinal disease increased, as there was an increasing liability to infection from improper or unwholesome food. In France one-half of the children below one year of age died each year from intestinal troubles. In three years eighteen thousand bottle-fed children died in Paris alone. The breast-fed did not escape entirely, but were less liable to intestinal infection. Nearly all children fed artificially got more or less cow's milk, and the many times it was handled gave many chances for infection, not only with animal filth but also dairy dirt, and particularly streptococci, which caused diarrhœa. The great medical congress of 1881 laid great stress on cleanliness. Soxhlet emphasized cleanliness in preserving milk. The greatest lights on the problem were those relating to cleanliness. It could be successfully accomplished in many ways. The foundation of infant feeding must be the mother's breast, yet this might vary from eighty-nine caloric equivalents to one hundred and twenty-six calories. The absolute quantity at the breast being unstable, our rules for artificial feeding must vary. Meigs showed that the proteids were usually low in mother's milk, and that the fats varied much. Leading minds differed as to how the variations should be accomplished: some diluted only; others, as Meigs and Rotch, reconstructed. Jacobi and others diluted, and added ingredients. The key-note of intestinal disorders was infection; therefore the sick children should always be separated from the well. We had as much responsibility in the intestinal infections as of prophylaxis in scarlatina or measles. The ignorant mother should be taught the possibility of carrying contagion, and that the utmost care should be exercised in washing thoroughly after changing the child's napkins, and that there be no rapid change from toilet oprations to feeding. The physician should have constantly in mind the distinguishing characteristics of stools, that he might know when streptococci had disappeared and when milk could safely be resumed. Cases might be treated as ambulatory, coming to a dispensary, or in hospitals and sanitariums. Those patients taken out of doors did best, as they had fresh air. The stools should be examined grossly and microscopically at a laboratory in connection with the dispensary. For ten years the speaker had so managed his intestinal cases; and two hundred infants daily, the year around, received their proper milk supply there at the dispensary. Increasing weight encouraged the mothers. Mothers should not be allowed to get prepared or modified milk except on a physician's order, as they usually overfed. Even water was furnished for the preparation of albumin water. It impressed upon the mother the necessity of attention to details. Examining the stools was not a fad. It was a sure way of determining the proper treatment and food. The speaker advocated, as the ideal management, the treatment of one or two cases only together, in barracks or camps or huts on high ground, not necessarily near the seas but inland. These tents or camps could be comfortable but very simple, warmed if need be by a stove. The mothers should live with the babies and take them once a day to the central camp, where the physician could see them and prescribe. Infections like measles and scarlatina were not likely to spread there, and intestinal infection would rapidly subside. Here was a new future for the summer management of the poor.

Studies of the Blood in Childhood.—This paper, by Drs. Alfred Stengel and C. Y. White, of Philadelphia, was read by title.

Intestinal Obstruction through a Loop Formed by Meckel's Diverticulum, with Ligamentous Attachment.—Dr. Irving M. Snow, of Buffalo, read this paper, and presented the specimen. The speaker stated that the cases were very obscure in many ways as to origin, formation, and symptoms. The case narrated was that of a boy, three years old, who fell from the doorstep and struck about the navel. A few days later he ate a quantity of grapes. The fall occurred on the 9th of the month; vomiting began on the 12th and lasted five days. There was pain about the navel, and opium was administered from the 14th to the 17th. The belly was slightly distended, but the temperature remained normal, and there was no abdominal tenderness. Vomiting of fecal matter occurred on the 17th. An intestinal injection with oil brought away a few grape-seeds and caused collapse. There was visible peristalsis of the intestines. At the autopsy no peritonitis was found. The ileum seemed to be snared close to the ileo-cæcal valve, and oil was found above the strangulation. One-third of the reported cases were of this character, but the condition was rarely seen in childhood. The obliterated portion of the omphalomesenteric duct created an arcade that readily caught the gut. The exact nature of the case was not recognized until after death.

In the discussion, Dr. Caillé, of New York, said that every case of chronic intussusception that had vomiting should be submitted to exploratory laparotomy.

Dr. S. S. Adams also favored early operation, basing his remarks on a recent experience. It was well known that usually hospital cases resulted fatally from delay. The case mentioned had the characteristic straining and screaming, but no tumor. Rectal examination proved nothing. Three drops of tincture of opium had been given, which completely narcotized the child. Next day, salt injections failing to relieve, operation was done. A profuse stool occurred while under anæsthesia, but the abdomen did not collapse. Four inches of intestine were found invaginated. The child made a complete recovery, though only five months old. Very few recovered without operation.

Dr. W. S. Christopher alluded to a case of his, of a child four months old, nursed at the breast, which suddenly showed symptoms of intussusception without cause and without fever. Blood was passed from the bowel, but there was no vomiting. There was neither tumor nor tenderness. At the operation one and a half inches of small intestine were found in the colon. Recovery was complete, the child nursing half an hour after operation, and six hours from the onset of the attack. Six months later the same symptoms occurred. The belly was again opened, and air injected with great force into the bowel. It did not budge, but this constituted a direct experiment not often possible. The invagination was reduced and the appendix removed. Recovery was complete as before. No double case has been found thus far on record.

Dr. W. L. Carr also emphasized the necessity of early operation even in the absence of symptoms. He recalled three cases during the past year without tumor, but with symptoms of ordinary colitis. One intussusception was found unexpectedly at an operation.

The Pancreatic Digestion of Casein.—Dr. B. K. Rachford, of Cincinnati, read a short paper on this subject. His experiments consisted in collecting fresh pancreatic juice from rabbits, also bile from rabbits, and placing the same in tubes with ordinary fresh cow's milk filtered and neutralized. These tubes were placed for five or six hours in a water bath at 38° C. Lactic acid and ammonia were used to complete coagulation of the milk, and the remainders were washed, dried, and weighed. Maltose was prepared by boiling one of the Liebig foods. As a result of these experiments it was found that maltose aided the pancreatic digestion of casein. It was also found that the presence of rabbits' bile facilitated the action of pancreatic juice. It increased the diastatic action when starch accompanied the casein. Dr. Jacobi had long taught that starchy gruels aided in digestion of the milk casein. The experiment with lime-water showed that it increased proteolytic action of milk in the stomach. Lime helped the activity of the rennet. In milk feeding, lime water not only neutralized acidity, but stimulated pancreatic digestion in the intestine. Sodium bicarbonate greatly increased the proteolytic power of pancreatic juice on casein. It also neutralized the fermentative acids of milk. Hydrochloric acid was found to retard proteolytic action. Bile and hydrochloric acid caused the pancreatic juice to act with greater intensity. The intestinal contents lost their acidity at some distance from the stomach. The fact that acid so strongly aided pancreatic action should greatly influence its use in infant feeding; besides being an intestinal antiseptic it aided the pancreatic enzymes. Greasy and fatty stools came from deficient bile supply.

In discussion Dr. Rotch stated that cereals, while having no retarding action, had but slight proteolytic action, and besides called up amylolytic action. He would be against their use. He did not regard the presence of fat in the stools as abnormal.

Dr. Caillé spoke highly of hydrochloric acid, which he had used for fifteen years in all cases in which the tongue was coated, especially in children two years old or more. When the tongue became clean, the acid should be stopped and iron given.

Dr. Fruitnight gave testimony in accord with the last speaker. He esteemed hydrochloric acid highly from many years' use of it.

Dr. A. C. Cotton spoke of the fact that fat as such was rarely found in the stools. Not all light flocculent masses were fat. It could be surely recognized only by chemical analysis.

Dr. Holt had seen little efficacy from any of these drugs. He claimed more for stomach washing. The use of drugs was purely empirical. Drugs played no part if the food was proper. Proper food should be given, the stomach washed, and the child kept in the fresh air.

Dr. Blackader confessed that the use of acid was contrary to our knowledge of physiology, as it was found late after eating, not immediately. Washing was troublesome. Catarrhal processes were present and demanded alkalies. Acids disappointed. The society should not emphasize the use of drugs, but the broad principles of management.

Dr. Rotch noted that it was necessary to dilute cows' proteids, as they went farther than those of human milk. Drugs should seldom be used.

Dr. Rachford called attention, in closing, to the fact that this was but an announcement of experimental facts and not a treatise on treatment in general. They threw light on pancreatic juice and what influenced it. Bile with pancreatic juice emulsified fats; this was destroyed when in contact with strong alkalies, and the fat was absorbed, not emulsified. Cream in the stools did not appear with its albumin and soap covering, but as butter fat. When hydrochloric acid was absent, it was needed and should be given. Clinical use in proper cases abundantly proved that it was not empirical treatment. Acid at most was an addition. It would not take the place of proper selection of food and of cleanliness.

Clinical Observations upon the Operative Treatment of Tuberculous Peritonitis.—Dr. Augustus Caillé, of New York, read this paper. Two points were of interest, the behavior of cases before operation and their behavior after operation. The cases narrated were mostly from the babies' wards of the Post-Graduate Hospital. In all cases examinations were made of the urine, blood, fæces, and puncture fluids. As an example, he gave the case of a boy, aged six years, with abdomen swollen, tense, not painful. Fluid was present. Rectal irrigation and creosote had been used for some time. Dr. Curtis operated and found the usual pathological nodules of tuberculous infection. Two years afterward the boy was well. The general abdominal cavity had not been encroached upon. Another case was that of a boy two and a half years old, who gave a negative history except a tumor on each side of the abdomen. These were found to be large tubercles, not adherent. No other glands were theninvolved. Eighteen months afterward small tumors could be felt there. In a third case, that of a girl aged five years, fluid was encysted as high as the umbilicus. At the operation adhesions and miliary tubercles were found covering the intestines. A sinus persisted for a year and closed. When it did so râles were found over the right lung. The sinus was curetted and cured and the lung also healed. She was now well. J. C——, another patient, had flatness due to a cyst, as high up as the umbilicus. It was opened and dressed with ten-per-cent. glycerin and iodoform. He was now healthy but pale. A girl, aged nine years, had pain in the abdomen for six months, with eight or ten stools each twenty-four hours. The blood and urine were normal. After two years' treatment an operation was done and disclosed adherent tuberculous peritonitis. The diarrhœa and paroxysmal pain had lasted two years. The speaker gave the following *résumé:* Diagnosis was based on pain, fluid, loss of weight, etc. Febrile rise was always found if careful observations were made. Bacilli were rarely found in fluids. The pain might be intestinal. He regularly employed the tuberculin test in human subjects. These cases showed the futility of medicine in tuberculous peritonitis. Early operation was always to be advocated. He was sceptical about complete cures.

Discussion.—Dr. Fruitnight mentioned the case of a young woman, aged twenty years, with an ulcer of the palm, which the microscope showed to be tuberculous. She had also recurrent peritonitis. He thought early excision of the lump in the hand might have spared the woman the general infection.

Dr. Rotch spoke of sixteen cases of tuberculous deposits found in patients dead of diphtheria. It showed how important in every way was tuberculosis to a pediatrist; particularly, that it should be kept out of the alimentary tract. If the case was one secondary to lung infection, laparotomy would do little good; if primary, it might cure. Certainly it would not give bad results. In one case followed for seven years the patient was now well. Secondary cases were the rule; hence bad results. Laparotomy was really more definite and at times less harmful than castor oil. One should never hesitate to make an exploratory incision. The bacteriologist had not kept up with the surgeon here. Many cases that we felt uncertain about were doubtless tuberculous. Cases without effusion did well. The vast majority of abdominal tumors were tuberculous. Tuberculous mesenteric glands must be removed to prevent general infection. When the trouble was secondary to tuberculosis of the lung it was a general, not an abdominal disease. He was strongly in favor of tuberculin for diagnostic purposes.

Dr. Cotton agreed that tuberculosis was paramount to any disease of childhood and very difficult to diagnose. He asked how far we could insist on an exploratory incision for diagnosis only.

Dr. Rotch replied that it should be done as a routine.

Dr. Johnston called attention to the absence of leucocytosis in differentiation from ordinary peritonitis.

Dr. Caillé, in closing, reiterated his statement that medicine was of no avail here. The abdomen must be opened. The other causes for ascites, as heart disease or cirrhosis, were easily eliminated.

The meeting adjourned to Wednesday at 9:30 A.M.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day—May 1st.

President's Address.—This was delivered by Dr. E. D. Fisher, of New York.

Christian Pseudo-Science and Psychiatry.—This was the title of a paper read by Dr. Smith Baker, of Utica. He reviewed the claims of healers and the cures they were said to have effected, and gave an analysis of the condition of mind and body commonly induced by the Christian Science healer. He found it to consist of a variety of imperative conceptions very difficult to manage. The conclusion reached was that these cases required a most comprehensive study of both the psychical and physical state in order that the proper cultural treatment could be instituted and maintained. This was the only method which would thoroughly cure.

Imperative Ideas in the Sane and their Management.—Dr. Edward B. Angell, of Rochester, read a paper on this subject. He said that imperative ideas were to be distinguished from fixed ideas, or delusions. The former involved the element of conscious and painful resistance in the *ego* against their acceptance; the latter were appreciated as real conditions and were accepted as true. In imperative ideas or obsessions the psychical reaction in feeling was against the idea; in the fixed idea or delusion it was in harmony with it. Imperative ideas were largely emotional in their character and related to abnormal sensations of a somatic character. They were dependent, however, for their manifestation upon a state of mental feebleness, an instability of mental synthysis. These ideas might affect either the sensorium, the motor sphere, causing impulsive acts, or produce vasomotor disturbances. The subjects of this mental vice might be divided into two groups—those whose mentality was dependent upon hereditary, congenital, and acquired defects of organization, the degenerates; secondly, those who through accidental causes became unduly subject to emotional disturbances, the weak-willed. In treatment it was the primary emotional state one should counteract. The morbid idea might be replaced by a real one through strong sensory stimulation. The idea might be altered by attaching to it some association, ludicrous or painful, in character. Isolation of the patient, education through diversion, and increase of the power of attention toward normal feeling and action, constant yet not too stimulating change of scene, all entered into proper treatment. In some cases hypnotism, which had enabled us to learn much regarding these morbid mental phenomena, might be utilized to advantage.

Dr. Smith Baker said that persistent mental stress on the part of parents was likely to predispose the child to imperative ideas. He was in favor of educational methods in preference to hypnotism.

Dr. P. C. Knapp, of Boston, did not agree with Dr. Angell's views as to the relationship between obsessions and imperative ideas. He did not approve of hypnosis in the treatment of such cases, but preferred educational methods.

Dr. S. Weir Mitchell, of Philadelphia, referred to a case of mania of repetition, in which the patient would repeat certain acts several times, and associate the number of times with the thought of various relatives. This was relieved by sudden pinching by her attendant at the time of the act, thus substituting another form of sensation for its relief. After many years of experience he was opposed to the use of hypnotism alone as a method of treatment. He knew of no case in which a cure had taken place by hypnotism alone, unassociated with other means.

Dr. B. Sachs, of New York, believed that imperative conceptions, so often morbid, were closely related to the psychological, and were often based upon some definite reasoning. They did not arise spontaneously. Hypnosis not only did not cure but originated such concepts.

Dr. J. J. Putnam, of Boston, thought that the original idea passed over into a mechanical symbol which influenced the patient. The use of suggestion without hypnotism was of value, but hypnosis itself was very valuable in certain cases.

Dr. W. Browning, of Brooklyn, said that imperative movements were somewhat similar. One type simulated melancholia and differed in the results of treatment. It could be successfully overcome by enlarging the mental sphere of the individual.

Dr. Angell, in closing the discussion, said that if the ideas were carefully analyzed much could be accomplished toward effecting good results. It was sometimes difficult to establish the difference between fixed ideas and imperative ideas. The latter were usually amenable to treatment. Hypnotism was of value as an educational method. American men and women, however, were not as susceptible to hypnotism as the French and German.

Wernicke's Conduction Aphasia with Autopsy.—This was the report of a case by Dr. Howell T. Pershing, of Denver.

Bullet-Wound of the Spinal Cord.—Dr. Joseph Sailer, of Philadelphia, reported the case of a Cuban officer who was shot through the spinal cord, the bullet injuring the fourth and fifth lumbar and the first four sacral segments. Three years after the injury a laminectomy was performed for the relief of fulgurant pains, and a pachymeningitis was found. The operation was successful. During convalescence allocheiria appeared and persisted for three days.

Dr. Weir Mitchell thought that the most remarkable feature in the case was the disappearance of the gluteal muscles. He had been the first to describe the symptom of allocheiria. It was at the time of the war, over thirty years ago.

Dr. J. W. Putnam, of Buffalo, referred to the case of a patient who had fallen and injured the spine, producing pain and rigidity in the cervical muscles. This was followed two years later by paraplegia and anæsthesia. There was deformity at the sixth and seventh vertebræ. Operation revealed fracture of the sixth cervical spine and thickened dura. Improvement followed. There was restoration of bladder function and sensation improved. Irritation applied to the lower extremity was referred to the seat of the injury.

The "Babinski" Reflex.—Dr. G. L. Walton, of Boston, read a paper on this subject, in conjunction with Dr. W. E. Paul. He had examined the plantar reflex of one hundred normal individuals, seventy infants, two hundred cases of nervous disease other than that of the pyramidal tract, one hundred cases with other than nervous disease, two hundred hemiplegics and diplegics, and thirty cases of pyramidal spinal disease. The following conclusions were drawn: (1) In health either of the following conditions might appear on taking the plantar reflex: (*a*) flexion of all toes; (*b*) flexion of some (generally outer) toes; (*c*) flexion of all toes on one side, and of some (generally outer) on the other; (*d*) entire absence of movement on both sides (about ten per cent.); (*e*) flexion of all or of some (generally outer) toes on one side, with absence of movement on the other (at least ten per cent.); (*f*) occasionally (in sensitive individuals) quick, semi-voluntary, indeterminate movements, sometimes of flexion, sometimes of extension. (2) In early infancy no constant or characteristic movement of the toe appeared, though extension was rather more frequent than flexion. (3) The Babinski reflex obtained in about seventy per cent. of hemiplegics and diplegics, and in approximately the same percentage of cases with disease involving the pyramidal tract in the spinal cord. (4) The Babinski reflex (deliberate and constant extension of the great toe, with or without extension and separation of other toes) was never present in health, and our observations led us to doubt its existence in either functional or organic nervous or other disease not implicating the pyramidal tract. (5) This reflex was oftenest the earliest to appear in pyramidal tract disease, *e.g.*, at the onset of a hemiplegic attack before the establishment of the exaggerated knee jerk and ankle clonus; it may persist during a period when other reflexes are absent, *e.g.*, when knee jerk and ankle clonus were wanting on account of ankylosis, contracture, and muscular wasting, as in long-standing diplegia, or of degenerative sequences, as in combined systemic disease. This reflex furnished, therefore, a most important practical aid in diagnosis. (6) This reflex very exceptionally appeared in cases not conforming to recognized types of pyramidal disease (meningitis, hydrocephalus, poisoning as by alcohol or uræmia). These instances were too few materially to impair the diagnostic value of the phenomenon—in fact, the Babinski reflex alone should here rather lead us to suspect pyramidal involvement as by œdema or indirect pressure.

Clinical Study of the Reflexes.—This was the title of a paper read by Dr. Joseph Collins, of New York. It was based on the study of two hundred cases. This and the preceding paper were discussed together.

Dr. Weir Mitchell said that the whole physiological literature on this subject came from this side of the ocean, since the Jendrassik method was first expounded. All muscle jerks were capable of re-enforcement as well as tendon jerks. He called attention to the fact that it was impossible to re-enforce the skin reflexes.

Dr. Knapp said that we did not know why the skin reflexes were so persistent in tabes. As to the normal plantar reflex, it was usually present unless affected by disease.

Dr. B. Sachs differed from the views of Dr. Collins and believed that the condition of the reflex did not depend on the tonus of the muscle. The Babinski reflex was most unreliable in children.

Dr. W. G. Spiller, of Philadelphia, referred to two acute cases of cerebral hemorrhage with hemiplegia, in which on the paralyzed side the knee jerk was absent and the Babinski reflex present. Both patients died. He was therefore inclined to look upon such a combination of symptoms as indicating a bad prognosis. Babinski's sign was of value only in connection with other symptoms.

Tumor of the Superior Parietal Lobule.—This was the report of a remarkable case by Drs. Charles K. Mills and W. W. Keen, of Philadelphia. The tumor was accurately localized and removed by operation. There were localized paræsthesiæ, astereognosis, and later hemiplegia. None of the general symptoms of cerebral tumor was present. The eye symptoms relating to the fields were suggestive of hysteria. The patient made a good recovery and was restored to usefulness.

Dr. Spiller stated that the growth was endothelioma.

Dr. Walton mentioned the case of a patient without any of the general symptoms of tumor. There were twitching of the hand and temporary paresis, later followed by hemiplegia. Subsequently, optic neuritis developed in one eye.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-second Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

President, Samuel Johnston, M.D., of Baltimore.

Opening Session—Tuesday, May 1st.

President's Address.—After returning thanks to the members of the association for the honor conferred upon him, the president spoke of the future policy of the association. He believed that new members should be elected by a two-thirds affirmative vote of the entire membership. Old members should be encouraged to continue in active work. Scientific and clinical work should go hand-in-hand. One should avail himself of all possible advances in diagnostic ability—as, for instance, the determination of leucocytosis as an initial feature of malignant disease. More attention should be paid, in teaching students in rhinology and laryngology, to operative work on the cadaver. Members of the association were looked to as teachers, and consequently great care should be taken in the selection of new candidates. The aim should be not mere numerical strength, but skill in attainment. In the programmes of the future it might be well to limit the number of papers, but more attention should be given to discussion. The former should be grouped in two general classes, scientific and clinical. No opinion should go out from the meetings as official unless it was founded on facts. Mild measures, especially as concerned the use of the cautery, saw, and trephine, should be strenuously urged. A committee of censors, to be elected annually, should be established which should pass on all matter to be published in the annual Transactions. In conclusion, a feeling tribute was paid to the memory of two active fellows who had died during the year—Dr. Max Thorner, of Cincinnati, and Dr. Joseph C. Mulhall, of St. Louis.

Fractures of the Nose.—This paper was read by Dr. T. A. De Blois, of Boston. He said that "broken" noses, so-called, were not, as a rule, really fractured. They were rather cases of bony displacement and dislocation. They might be classified according to the degree of injury and also according to the relation of the parts involved. There might be a dislocation (not fracture) of the nasal bones, *i.e.*, a solution of bony continuity, or there might be a fracture of the nasal process of the superior maxilla or of the zygoma. Injuries might also result during parturition or from nursing or sleeping, from the constant impact of the nose, delicate at this period, against the mammæ or the pillow. Then again there were the cases occurring from falls, blows, and collisions. In the "upper-cut" blow of the boxer, there was injury to the septum, followed by swelling, possible abscess, and detachment from the subjacent parts. The "side" blow gave a double dislocation of the nasal bones, while in the direct "front" blow the internal nasal border was driven downward and outward. Treatment consisted in the reduction of the dislocation, which might require a general anæsthetic. These flat noses might be properly manipulated so as to dispense with external apparatus. For an internal splint, a bit of stiff rubber tubing inserted by means of a closed pair of scissors (well greased so as to facilitate their withdrawal) might be of service. The elastic recoil of the rubber slowly acting will often force a dislocated nose into place, though some few days might be required to produce the full effect. Plaster-of-Paris bandage made an excellent external splint. Illustrative clinical cases were then described.

Dr. De Blois also exhibited an illustration of an abnormality of the uvula, which was double, one mass seeming to come from the anterior and the other from the posterior faucial arch. The former was amputated, leaving the latter appearing as a perfectly normal organ.

Dr. Emil Mayer, of New York, inquired of Dr. De Blois if he had not found the rubber internal splint irritating to the nasal mucosa. He himself preferred to use gutta-percha, which could be accurately moulded to fit each individual case, and was less collapsible. Elongated forceps could be used for the replacement of recent cases.

Dr. De Blois replied that the rubber was to be retained only temporarily, until perfect reduction had been secured.

Dr. W. E. Casselberry, of Chicago, recommended the use of a general anæsthetic for perfect diagnosis and reduction. Deeper injuries were very painful, and in children without an anæsthetic proper examination was impossible. He commended the external plaster-of-Paris dressing. The objection to all forms of special apparatus was that they were rarely at hand when wanted, and were difficult to keep in position. Plaster could be moulded over the nose, carried back to the line of the ears, being made thinner posteriorly, and secured by tapes passing above and below the ears behind the head. Such splints had to be worn ten days, and were, of course, a disfigurement. For internal splinting nosophen gauze applied under cocaine acted admirably. For fractures low down in the nose, the ordinary vulcanized tube answered very well.

Dr. Jonathan Wright, of Brooklyn, called attention to the statements found in the writings of the fathers of medicine respecting the treatment of nasal injuries. The fingers of a child, thongs attached to plugs on the concave side of the injury, etc., had all been advocated. In a recent case, one authority had inserted a plug made from the lung of a sheep. All the ancients objected to the use of absorbent material as rapidly tending to become foul.

Dr. John O. Roe, of Rochester, commended the use of a thin metal splint externally with an internal dressing. An anæsthetic should be given when the injury was at all severe. Adhesive plaster was an admirable retaining material.

Dr. H. L. Swain, of New Haven, Conn., called attention to the mechanics of the nasal arch, saying that if one could bring the two nasal bones into proper approximation, they would support each other. If the patient could be seen frequently, he would dispense with all apparatus.

Dr. F. C. Cobb, of Boston, had had as good results without as with apparatus. The behavior of the nose during the first two days after the receipt of injury would determine whether or not apparatus might be safely dispensed with.

Dr. W. K. Simpson, of New York, advocated the use of the Bernays sponge specially shaped to fit the inside of the nose. It offered ideal requisites for this purpose, being easy of introduction and hæmostatic by the equable pressure it exerted.

Dr. W. F. Chappell, of New York, had used the sponges, attaching them by iodoform collodion to a thin plate of gutta-percha, a device which had, in his hands, proven of great value.

Atrophic Rhinitis.—Dr. J. E. Logan, of Kansas City, Mo., read this paper. He reviewed the various theories of the pathology of this condition, condemning the introduction of the very large number of clinical terms which had been used to describe it. Four theories as to causation seemed worthy of special consideration: (1) hypertrophy, cutting off the blood supply by pressure, thus inducing atrophy; (2) suppurative rhinitis in children; (3) bacterial causation; (4) sinus disease. For himself, he was inclined to attach importance, on the basis of his own experience, to the last-named theory. He narrated the histories of several cases in which opening and curetting of the ethmoid cells cured the atrophic rhinitis. One unexplained fact in these cases was the real source of the immense amount of secretion.

Dr. Cobb had observed in his own ethmoid cases marked atrophy on the side of the sinus disease. In persistent sinus discharge he had noted a steadily increasing atrophy of the intranasal structures.

Dr. Wright stated that post-mortem examination did not show that close connection between atrophic rhinitis and sinus disease that had been claimed by Grünwald and others. In his own personal experience, the inferior and not the middle turbinate was the structure primarily attacked. The etiology of atrophy here was hard to determine. There was no analogous process in any other part of the body. He was inclined to attach much importance to the recent views of Cholerva and Cordes, who looked upon the process as the result of a rarefying osteitis, commencing with a bony hypertrophy, the little canals in the bone containing an artery and vein becoming occluded by the bony growth. As a result the blood supply to the mucosa was shut off. How this process actually began was a matter of much less importance. Recent anthropometric investigations had confirmed Hopman's view as to the causative relation of a short antero-posterior nerve dimension, and still more strongly Fraenkel's contention as to the special occurrence of the affection in the brachio-cephalic type of skull. This latter observation, however, might be referable only to certain geographical areas, especially in Germany and Switzerland, and not applicable to American patients. No one cause was alone applicable in every case. In his own experience, seventy-five per cent. of the cases had occurred in women, and the sexual life might be an important factor.

Dr. Swain called attention to the fact that the rarefying osteitis had been marked as the cause of intranasal œdema and polyp formation, but he realized that intranasal conditions might differ in different types of skulls. The brachio-cephalic type of naris might cleanse itself with more difficulty than would other types.

Dr. J. E. Boylan, of Cincinnati, inquired if Dr. Wright had ever seen patients spontaneously recover after the menopause.

Dr. Wright answered that he had noted a cessation of symptoms, while the objective atrophy remained.

Dr. Casselberry declared that we must not overlook the associated atrophy of adjacent parts; there was also an atrophy of the lymphoid structures, a nonsensitiveness of the parts, and either a lack of development or an early shrinkage of physiologically associated tissues. The bony walls of the sinuses were especially thin in these cases. All of these lesions strongly suggested to him the theory of a tropho-neurosis.

Dr. Simpson had seen cases persisting beyond the menopause with as much virulence as before.

Recurring Membranous Rhinitis due to the Bacillus of Friedlander, with Report of a Case.—This paper was read by Dr. Emil Mayer, of New York. The clinical history of the case described was a later chapter of the case previously reported before the American Medical Association by Dr. McReynolds, of Dallas, Tex. After the case came under Dr. Mayer's observation exhaustive microscopical and bacteriological tests were made, proving to his own mind that the membranous formation was due to the bacillus of Friedländer. Some thirteen or more previous cases were on record and were carefully analyzed by Dr. Mayer, who gave a complete *résumé* of the literature of the subject.

At the close of the session Dr. Boylan exhibited a hypodermic syringe for the application of cocaine to the pharyngeal vault for adenoid operations.

Dr. J. H. Bryan, of Washington, showed an aseptic syringe for nose and ear work and improved drainage tubes for the frontal sinus; Dr. R. P. Lincoln, of New York, a wax model of a recurrent tonsillar tumor with illustrative plates; Dr. Mayer, a hollow intubation-tube introducer for use in laryngeal stenosis, the intubation tube itself being retained by an arm screwed in through the tracheotomy incision.

Dr. T. R. French, of Brooklyn, exhibited photographs of a chair to be used in the employment of the upright position in ether operations on the nose and throat.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Fourteenth Annual Meeting, Held at the Raleigh Hotel, Washington, D. C., May 1, 2, and 3, 1900.

President, James Bell, M.D., of Montreal.

First Day—Tuesday, May 1st.

Chronic Pyelonephritis and its Pathogenic Relation to Diseases of the Opposite Kidney.—Dr. John P. Bryson, of St. Louis, Mo., read this paper, and his observations suggested the following conclusions: (1) Post-operative observation in a number of cases of primary unilateral nephrectomy, as well as secondary nephrectomy after nephrotomy and drainage, seemed to confirm the belief that long-continued unilateral pyelonephritis had a pathogenic effect upon the previously unaffected kidney of the other side. (2) This pathogenic relationship seemed to hold good even when the primarily diseased organ was adequately drained either by the ureter or by a renal fistula. (3) Observations, as yet inadequate, seemed to show that the pathogenic effects upon the organ secondarily diseased manifested themselves primarily in the tubular epithelium, determining a parenchymatous nephritis. (4) Suppurative pyelonephritis seemed to add the element of amyloid degeneration to the secondary nephritis; but whether this change took place in the kidney before other viscera well known to be commonly affected in this way by chronic suppuration became involved, was wholly undetermined. (5) The mechanism of this secondary nephritis was not yet determined. Whether it was caused by the "reflex" action through the nervous system, or by the absorption of toxins or bacteria from the primarily diseased kidney carried by the blood stream to the other kidney, increasing its burden of elimination, and thus irritating the tubular epithelium, seemed to be a question for the experimental laboratory. (6) So far as our information went at present, it served to increase the probable benefit of frequent observation of the segregated urines, which might serve not only to localize the disease, but to determine the time of surgical interference by giving warning of the beginning of crippling of the previously healthy kidney. (7) Repeated observation of differentiated urines had a distinct prognostic value in surgical intervention, even to the extent of influencing the choice of nephrectomy and nephrotomy.

Some Observations upon Hydronephrosis.—Dr. A. T. Cabot, of Boston, read this paper. He instanced the history of a boy, eleven years of age, who during the past nine and a half years had had repeated attacks of severe abdominal pain. During these attacks it was noticed that there was a swelling in the left renal region which diminished with the subsidence of the pain. These attacks were accompanied by fever and vomiting. During later years the attacks lasted a number of days. The diagnosis of hydronephrosis, already made, was concurred in and operation advised. The operation showed it to be a case of ruptured hydronephrotic sac with a pseudo-hydronephrosis around it. The rent in the dilated kidney was closed in the hope that the urine would re-establish its passage through the ureter, as had happened often before. This hope was not gratified. At the end of twenty-four hours the pseudohydronephrotic sac filled and became very painful; then the hydronephrotic sac was again opened and a drainage tube was introduced, which was followed by complete relief, and the boy gradually recovered his strength. In this way he lived for two years without pain, when he entered the Massachusetts General Hospital for the relief of the urinary fistula. Before proceeding to operation it was thought wise to increase the secretion of the kidneys, which were acting insufficiently. As the hydronephrotic kidney was discharging all of its urine through the fistula, it was possible to collect the secretion from each organ separately, which was done. It was interesting to note how much good work was done by a kidney in which the secreting substance was stretched out to a mere shell on the surface of a hydronephrotic sac; also, how decidedly this work could be increased by the diuresis produced by the exhibition of large quantities of water. By this simple diuresis the total amount of urine was increased from eighteen to seventy ounces, and the amount of urea was increased from 11.07 gm. to 16.73 gm. Having improved the condition of the patient, the hydronephrotic sac was exposed and stripped off from the surrounding tissues. When the hilus was reached, the ureter was readily recognized, and the following condition was made out: The ureter, of normal size, after leaving the pelvis of the kidney, pursued the ordinary course toward the bladder for a distance of an inch, when it turned backward and upward to loop itself over an accessory artery which ran from the aorta and entered the kidney at a point somewhat below the origin of the ureter. This loop was S-shaped, and while the canal was of nearly normal size above the point where it hung over the vessel, below that point it became very narrow with extremely thin walls. The ureter could not be followed with a probe, and it was shown that this undeveloped condition of the ureter continued down toward the bladder. It was then decided to remove the kidney; this was done, and the patient made a good recovery.

Dr. L. Bolton Bangs, of New York, said that two years ago he operated upon a gentleman who seemed to be in an extremely dangerous condition; he was septic from a prostatic abscess which had opened into the rectum; there was a residual abscess left which drained through the perineum. There was an extensive pyelitis, and the man seemed to be dying from a suppurative left kidney. There were evidences of the right kidney being distinctly enlarged; it could be felt. The left kidney seemed to be the one most dangerous to the patient, and it was decided to operate upon him. The left kidney was drained through the loin, and the patient made an excellent recovery. There did not seem to be any evidence of disease of the right kidney, although what would have been the result of a careful microscopical research he could not say; so far as was evidenced by his general condition and the urinary findings there was no disease of that kidney. He wore a tube in his right groin. He had gained ten pounds in weight; he travelled; he was becoming plethoric; he was not incommoded by his sinus, and he refused positively to have anything done further. In this case there was apparent recovery of the diseased kidney, which, so far as an examination could determine, was diseased before operation. Hydronephrosis was not a simple infection; it manifested itself in many ways, and this was an interesting question, bearing, as it did, on the etiology and treatment. One year ago he had had a lad brought to him who gave a history somewhat analogous to that read by Dr. Bryson. The urine was segregated by Harris' method, and it was determined that the case was one of hydronephrosis of congenital origin. The patient was running down so rapidly that it was decided to do a nephrotomy for drainage purposes. As the large sac was cut down upon, he was much astonished at the gush of blood that followed. The finger in the kidney sac revealed a large kidney which bled freely while it was being palpated. The sac was held open and deluged with hot water, which stopped the hemorrhage. He was thus drained for one year. He recovered, and many observations were made upon him as to the urine and the elimination of different things. When urotropin was administered by the mouth, each kidney would eliminate formaldehyde, as determined by appropriate tests. This showed that the statements made regarding urotropin were true. The question of secondary nephrotomy came up; as the work of excreting urea was being well done, he refused to do a nephrotomy until it was demonstrated that the other kidney could do extra work if required. Two weeks ago he did a nephrotomy. Instead of dividing the muscles, he separated them and came down upon the ureter and kidney with comparative ease. The operation proved to be quite a formidable one; the kidney tissue bled much, and he had simply to wrap the kidney up for a few minutes and squeeze it while the adhesions were being separated. He had to leave a portion of the tunica propria. The patient suffered a good deal from the shock, and had to be given salines repeatedly. Within the first twenty-four hours ninety-eight ounces of urine was excreted. A large amount of urine was excreted by that kidney, this urine being of a low specific gravity; when the saline was stopped, the amount was reduced to fifty-three ounces, and one day but nineteen ounces was excreted; it then ran up to twenty-seven and thirty ounces and thereabouts. The saline solution was given per rectum. He could not account for the condition of hydronephrosis.

Dr. George Chismore, of San Francisco, recalled a case that had been reported to this society early in its career. The patient was a young man who was seen early in 1870 with Drs. Keyes and Van Buren. He had severe illness, lasting several months, with symptoms mainly referable to his bladder; this was followed by lumbar abscess, which was opened; this abscess filled again, and was again opened, and at last he made a recovery. The condition of the remaining kidney certainly was an interesting question. In 1877 the patient was apparently in the last stages of consumption. In addition to his renal and bladder trouble he had a large fistula, apparently of tuberculous origin. In course of time this healed spontaneously. There had always been albumin in the urine, and there was to-day a certain amount of it present. After a lapse of nearly thirty years, he was still living.

The Pathogeny of Gonorrhœal Pyelonephritis; Presentation of a Gonorrhœal Kidney.—Dr. Bransford Lewis, of St. Louis, Mo., presented this specimen. He stated that it was possible for the infecting agent to reach the kidneys in three ways: (1) ascending infection by continuity along the mucous membrane of the urinary tract; (2) ascending infection through the lymphatics accompanying the ureter; (3) metastasis or general infection. The specimen presented was infected along the mucous membrane of the urethra, bladder, ureter, and thence into the renal tubules. He stated that gonorrhœal nephritis from an infection occurring through the lymphatics and blood systems was an established fact. Many authors, including Souplet, Jacquinet, Balzer, and Geraud, looked upon albuminuria, aside from that for which pus would be accountable, as one of the principal symptoms of the disease. In four hundred and twenty-four gonorrhœal cases, Balzer and Souplet found albuminuria ninety-nine times; in twenty-one of these cases they were uncomplicated otherwise, but in seventy-three of them there was orchitis. In this series it had been noticed that albuminuria was especially liable to occur in the cases in which there was the complication of orchitis; from this was deduced the belief that the danger of renal complication was augmented in proportion to the extent of surface involved in the complications of the urethral gonorrhœa. The greater the surface involved, the larger was the port of entry for the general infection.

Dr. Young, of Baltimore, and Dr. James P. Tuttle, of New York, discussed this paper.

The Modern Urethroscope: its Value and Limitations.—Dr. W. K. Otis, of New York, read this paper, and demonstrated many urethroscopic instruments. One instrument referred to was adapted to the Klotz form of tube by placing at the distal end a small, flat foot, at the outer extremity of which was a smooth pin. This pin fitted into a hole in the tube plate, and on revolving the instrument a quarter of a circle the foot swung under a shoulder riveted to the plate and was securely fastened. This joint was firm and easy of manipulation, readily allowing the illuminator to be attached or removed at any time during the examination. The fault of this instrument was that it still permitted the escape of a large amount of extraneous light, which soon became annoying to the eye of the operator. On this account he abandoned this instrument, and in 1892 devised one on an entirely different principle, using a lens as a condenser instead of the reflected light from a concave mirror. This instrument consisted of a metal tube or cylinder, an inch and a quarter in length by one-half an inch in diameter, closed at one end. A quarter of an inch from the open end was a plano-convex lens, so arranged that it could easily be removed for cleaning. On the interior surface, near the closed end of the tube, an elbow was let in, a quarter of an inch in length and half an inch in diameter, through which the source of illumination was introduced, a row of holes being bored at its base to allow of ventilation. The handle of the instrument was a piece of hard-rubber, with electrical connection running through it to the lamp placed on top. This handle fitted into the elbow by means of a bayonet joint, bringing the lamp immediately behind the plane side of the lens. A thumb-screw switch in the handle placed the lamp under control so that it could be turned off at pleasure. The instrument was attached to the urethroscopic tube by a stout wire an inch and a half in length, with hinged joints at each end which swung in opposite directions, and furnished with set-screws, thus allowing it to be put in any position, though when once adjusted it was rarely necessary to move it. This instrument had stood the test of some eight years' continuous use, and had demonstrated its superiority over all others designed for the practical examination and treatment of the urethra under direct ocular inspection.

(To be continued.)

Therapeutic Hints.

Anaphrodisiac.—

℞ Lupulin	10 gm.

For ten powders. S. Take one at bedtime.

Elixir of Paraldehyde.—

℞ Paraldehyde	10 gm.
Syr. menthæ	20 "
Elix. aromat	40 "
Aquæ destil	80 "

M. S. Teaspoonful once or twice daily.

Hemorrhoids.—

℞ Exalgin	0.30 cgm.
Ext. bellad	0.10 "
Ceræ alb	1.0 gm.
Ol. theobr	3.0 "

For one suppository.

Stomach Pains.—

℞ Morphin. hydrochlorat	0.02
Syr. simp	30.
Aq. chloroformi sat	60.
Aq. aurantii flor	60.

M. S. Dessertspoonful at onset of attack.

Picric Acid in Chronic Urethritis.—Begin with half of one-per-cent. solution and gradually increase to ten-per-cent. strength. Apply by means of a Guyon injector. Contraindicated in the acute stages.—Desnos and Guillon.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO , 51 Fifth Avenue

New York, May 5, 1900.

NATIONAL QUARANTINE.

AT present there is enough of intention on the part of Congress to effect some legislation in national quarantine matters, as is manifested by the different bills presented, but so far the indications for practical results are not very promising in view of the fact that there is not much time left for the different parties in interest to fight over the varied issues at stake. It is not so much the ends aimed at that invite criticism, for these in the main are laudable enough—as regards national quarantine as a whole—but the means by which they can be brought about. The question of actual result must narrow itself down to one of pure expediency.

So far there are three important bills before the House which deserve consideration regarding the prospects of passage. The one fathered by Senator Spooner is virtually the same as that under the same name that was before the last Congress. Its effect is practically to relegate all quarantine to State and local authorities. Mr. Ray has introduced its counterpart in the House. Another bill has been presented in the House by Mr. Mahon, and still another by Mr. Vest in the Senate, the latter being backed by the Marine-Hospital service. The prospects for the passage of either are narrowed to the possibilities of reconciling the interests of parties who appear to be diametrically opposed to each other. Virtually it comes to the question whether the local authorities with States' rights as their plea shall have control, or whether the general government as more directly represented by the Marine-Hospital service shall effect the unification of the forces. In one way it must be confessed that in the attempts to better present conditions the bills favoring widely varying interests are cumbersome in the extreme, and are very liable to fall by their own weight. They would seem in a general way to verify the danger of too many cooks for the broth. Thus Mr. Spooner's bill advocates the creation of a commission of public health composed of representatives from every State and Territory, and an executive or controlling body consisting of nine members, also from different sections of the country. With the very laudable purpose of educating the public on sanitary matters and of securing uniform legislation in the different States, the commission is loaded with so many special directions for work, so much conference with local authorities, and withal so much detail and red tape regarding other details, that, should an epidemic actually appear, there would be more time spent in getting ready to act than in doing the real thing necessary. Mr. Mahon's bill is obviously open to the same objection, only perhaps in a more marked degree, as by its provisions the country is divided into health districts, each having its respective head. While none of the measures is positively objectionable in either bill, the difficulties in making them work harmoniously in the required direction is apparently very great. In times of emergency the surest means to the end are the speediest and simplest. In trying to accomplish too much we may gain nothing in the end.

Almost by a natural conclusion it would appear far safer, instead of striving after vague and impossible reforms, to content ourselves by improving such systems as we may have at hand. From such a point of view the bill of Mr. Vest advocating the imposition of extra duties and increased powers on the Marine-Hospital service is worthy of very favorable consideration.

The bill amends a section of the law of 1893 so as to provide that upon the arrival of an infected vessel at any port not provided with proper facilities, the Secretary of the Treasury may send her to the nearest national or other quarantine where proper facilities exist, and, after the treatment of an infected vessel (or the inspection of a vessel not infected) at a national quarantine station, she shall receive a certificate which shall entitle her to entry at any port named in the certificate.

At any port where sufficient quarantine provisions have been made by State or local authorities, the Secretary of the Treasury may direct vessels bound for that port to undergo quarantine at the State or local station.

The bill adds also a very important section to the present law—empowering the supervising surgeon-general of the Marine-Hospital service, with the approval of the Secretary of the Treasury, to designate and mark the boundaries of quarantine grounds and anchorages, and officers of vessels or other persons trespassing on such grounds or anchorages are to be subject to arrest and to a fine of not more than $300, or imprisonment for not more than one year, or both.

There is nothing in the law forbidding the establishment of a State quarantine, notwithstanding a national quarantine be established, and this will only prevent the annoyance of a subsequent inspection, with a charge for the same, by the local quarantine, after the vessel has been thoroughly inspected and given a certificate by the national quarantine officer.

The provision relating to vessels arriving within the limits of any collection district of the United States without a bill of health, is meant to apply particularly to fishing-smacks and other small craft which leave Havana and other Cuban ports, and, under the guise of fishing, come within the collection districts of Florida and there land any sick who may be aboard, and smuggle aguardiente, rum, and tobacco, thus holding communication with the shore and being liable to convey infection. These small vessels are particularly dangerous, inasmuch as they are manned by laborers recently from Spain and who are, therefore, not immune to yellow fever, and lie in the portions of Havana harbor particularly exposed to yellow-fever contagion. The effect of this section will be not only to prevent the introduction of contagious disease, but also to suppress smuggling.

Another section authorizes the Secretary of the Treasury to establish quarantines at points of danger either on the coast or on the Mexican or Canadian borders. The necessity of having this authority is self-evident. Under the present law, to establish a quarantine requires either that there should be no State quarantine regulations in existence, or the demonstration and proof of inability or negligence to enforce such regulations as the Secretary of the Treasury has made, meanwhile leaving opportunity for disease to enter while the subject is under investigation or dispute.

Aside from the good features of the Marine-Hospital bill already noted it is gratifying to know that no attempt is made to legislate on any matters save those that relate to maritime and border inspection. Altogether it would appear that the latter bill, being the simplest and most practical one, has the best chance for its passage.

RELATIVE EARNINGS OF THE PROFESSIONS THROUGHOUT THE WORLD.

THE law is probably the most profitable of the so-called learned professions. There are more and larger prizes to be gained by an acute and eloquent disciple of the legal art than are open to the medical man or the minister. In this country and in Great Britain the incomes of the foremost advocates and of attorneys in lucrative practice for the most part overshadow the yearly earnings of the best-known physicians and surgeons, and to a still greater extent those of our spiritual advisers. Occasionally one hears of very large fortunes being left by prominent doctors—Sir William Gull, Sir Andrew Clarke, Dr. Pepper, and Sir William Jenner are cases in point; but these are exceptions, and sums accumulated by medical men cannot be compared either in number or magnitude to the colossal amounts amassed by members of the legal fraternity. When, however, the average incomes of these three classes of the community are considered, their relative position in the United States and in Great Britain will be found to differ. Viewed thus in the United Kingdom the clergyman is at the top of the list, the lawyer second, and the doctor last; while here the lawyer or doctor gets a larger share of the "loaves and fishes," and the minister has to be content with the crumbs.

An article in *Medicine* for April refers to a recent editorial in the Chicago *Times-Herald*, discussing the relative incomes of Chicago doctors and lawyers, which says: "It is doubtful if the average income of lawyers in Chicago is $1,500, but that is because the average is reduced by the large number of failures and of lawyers who scarcely make their board during the early days at the bar. There are a few law firms in Chicago which make from $50,000 to $100,000 a year; perhaps twice as many from $25,000 to $50,000; many more from $5,000 to $25,000; perhaps five hundred from $2,000 to $5,000, and the multitude from $2,000 down to nothing. Of physicians the same is true on a reduced scale. We doubt very much if the average income of doctors in Chicago is $2,000. The city is full of young M.D.'s without enough practice to give them a personal atmosphere of disinfectants. One or two successful specialists may make as high as $50,000; but the fingers of one hand would probably keep track of the regular practitioners who can count on $25,000 a year."

The average income of a physician in large cities on this continent may be placed at $2,000, in the smaller towns at $1,500, and in the rural districts at $1,200. Two or three New York physicians are said to make over $100,000 a year, five or six about $50,000, but the average income, although rather higher than in Chicago and in other American large cities, does not greatly exceed $2,000 yearly. The minister averages in the city perhaps $1,200, and in the country certainly not more than $800 yearly. As regards living expenses, both the lawyer and minister have an advantage over their professional brother. In New York, for example, office accommodation suitable to a physician is very dear, in a good neighborhood costing not less than $70 or $80 a month, which with board and lodging and other necessary disbursements will represent a sum of $120 monthly, a sufficiently weighty burden for a struggling youthful practitioner to bear. The young minister has no rent to pay, while the legal neophyte can regulate his outlay in this respect according to the length of his purse. Nevertheless the lot of the medical beginner compared with that of a pastor in a like situation has its compensations. He is at least more or less independent. The minister, on the contrary, is as a rule permitted to exercise his own will but to a limited degree, and often is doomed to go through a lifetime of toil, subservient to the caprices of censorious elders and deacons. An excellent description of the trials of an American country minister, and the various unpleasantnesses with which he has to contend at the hands of his congregation, is given in the "Damnation of Theron Ware," the best novel written by the late Harold Frederic.

When all is said that can be said, the first few years of medical practice are years of arduous effort, full of disillusionment and disappointment. The late Sir Andrew Clarke told Dr. Osler: "From the vantage ground of more than forty years of hard work he could say that he had striven ten years for bread, ten years for bread and butter, and twenty years for cake and ale." The truth undoubtedly is, and especially in the large centres of population in America, that the opportunities for a physician to obtain adequate compensation for his services are yearly becoming less. This is not due to any deterioration in the quality of the present-day practitioner or an evidence of falling-off in medical or surgical skill. The fact is irrefutable that the medical profession in this and in all civilized countries stands on a higher plane in the matter of training and knowledge than ever before. The reason for the decrease in medical incomes is indubitably almost wholly owing to the more eager competition among regular practitioners, to hospital and dispensary abuse, and to the lamentable increase in quackery. The supply of medical men is greater than the demand; the market is flooded, and the most potent remedy we can suggest for this evil is that, as has been many times advised in the MEDICAL RECORD, a uniform high standard of medical education should be established in every State.

THE DINNER TO PROF. A. JACOBI.

THE complimentary dinner which will be tendered to-night to our esteemed townsman, Prof. A. Jacobi, in celebration of his seventieth birthday, will give proper expression to the kind and appreciative regard in which he is held by his hosts of friends. Few men have been spared to labor so effectively as physician, educator, and civic reformer for nearly half a century, and few indeed have during such a period lived to better purpose. The kindly words which will be spoken and the hearty good wishes that will be offered by those who may gather at the festive board will at the best be but faint reflections of the host of his distant friends everywhere, who, while absent in body, will be present in spirit. On behalf of these making the large and unseen majorities, and representing the profession at large, we tender our hearty congratulations.

News of the Week.

A Threatened Milk Famine in Syracuse.—A despatch to the New York *Sun* states that the milkmen of Syracuse, N. Y., have determined to serve no more milk in that city until a recent requirement of the board of health, enforced by the commissioner of public safety, forbidding the issuance of licenses except to dairymen who can show certificates of the tuberculin test of all their cattle, has been rescinded. The associated dairymen, who furnish the city's milk, adopted resolutions and signed a compact binding them to this course. The dairymen assert that their herds have been injured by recent tuberculin tests, many cows which have been tested having been found dead without apparent cause. They say that the test is still an experiment, and that they will not submit to the health board's requirements. They will sell milk at their farms to such persons as wish to go there and buy, but they will not bring it into the city until the rule has been repealed.

The Health Board and the Schools.—The principal of a private school in this city has recently made a public complaint of remissness on the part of the board of health, alleging that the department neglected to notify him of cases of contagious disease in the families represented in the attendance of his school. An investigation has been ordered by the sanitary superintendent. It is stated, however, that there is no law making it the duty of the board of health to notify the principal of a private school of illness in the families of his scholars. There is a law, however, enjoining upon the principals of all schools, public and private, not to permit any child or minor having scarlet fever, diphtheria, smallpox, or any contagious disease, or any child in any family in which any such disease exists or has recently existed, to attend the school until the board of health shall have given its permission.

Dr. Otto G. Ramsay, of the Johns Hopkins University, has been appointed to the chair of gynæcology at the Yale Medical School to succeed Prof. B. Austin Cheney, who has recently resigned.

Dr. William C. Braisted, U.S.N., surgeon on the *Detroit*, has been decorated by President Castro with the Order of Bolivar for services rendered the wounded of the Venezuelan forces at the taking of Puerto Cabello in November of last year.

Medical Practitioners in Great Britain and Ireland.—The recently issued "Medical Register" for 1900 contains 35,836 names as contrasted with 35,057 names last year; ten years ago it contained 28,348 names. Complaint is made, however, that the lists are very faulty, the names of many dead men being on the roll.

Latin Diplomas Forbidden in Germany.—It is reported from Berlin that Emperor William has empowered the Prussian minister of education, Dr. Studt, to forbid hereafter the use of Latin in all university and faculty degrees, assigning as a reason the importance of a "more general use of the German tongue." An order to this effect has just been issued.

Cholera Accompanies Famine in India.—A despatch from Bombay, dated April 27th, states that cholera is raging fearfully at the great camp at Godhrá, where thousands of stricken natives are receiving relief. A hundred and fifty corpses were removed in one day, but one hundred others had to be left because it was impossible to procure bearers.

Glanders on an Army Transport.—The transport *Siam*, which sailed from San Francisco March 11th with a consignment of three hundred and eighty-six horses and mules, arrived at Manila on April 26th, and was placed in quarantine owing to the fact that seventeen cases of glanders have developed among the animals on board.

Priority in the Serum Diagnosis of Typhoid Fever.—Dr. Albert S. Grünbaum, of Vienna, writes to *The Lancet* making a claim of priority in the discovery of the agglutination test of typhoid fever. In support of his contention he produces a document signed by Nothnagel and Mannaberg in which it is certified that Dr. Grünbaum at the commencement of the year 1896 made systematic experiments with the material of one of the wards in the Vienna General Hospital on the agglutination of typhoid and cholera bacteria by serum taken from sick and healthy persons. It is stated further "that in March, 1896, therefore long before the publication of M. Widal on this subject, he had observed in two cases of typhoid in the ward that their serum, in considerable dilution, agglutinated typhoid bacilli. Dr. Grünbaum was fully aware of the diagnostic utility of this observation, and he delayed publishing it only on account of regard to the necessity of confirming the reliability of the reaction on a larger number of cases of typhoid. Dr. Grünbaum therefore discovered the agglutination reaction of typhoid serum independently, and to acknowledge this is a matter of justice." In these rapid times scientific workers have presented to them the disagreeable alternative of perhaps speaking too quickly, as Koch did, or of running the risk that some one else will anticipate the publication of the discovery and take the credit, as may be the case in this instance.

Honor to a Surgeon.—The Victoria Cross has been conferred on Surgeon-Major William Baptie, of the British army, for attending the wounded under fire at Colenso and for bringing in a wounded officer from the battlefield. Major Baptie was under a heavy fire all the time, and his horse was hit three times.

Dr. Edward J. Messemer was tendered a dinner on April 21st by the dispensary staff of Mt. Sinai Hospital, in honor of the twenty-fifth anniversary of his connection with the dispensary. Over thirty of his professional friends were present, Dr. Henry S. Stark occupying the chair as toastmaster. Congratulatory addresses were made by Drs. Mannheimer, Max Rosenberg, and Nathan Oppenheim, and original poems were read by Drs. Brickner and Rheinthaler.

The City Hospital for Consumptives.—Dr. Alfred Meyer writes that in Dr. Henry's bill, to which we referred recently, there is no provision for the appropriation of money by the State for its maintenance. The bill provides that a hospital which is for residents of this city may be built outside of the city limits but at the expense of the city, which is authorized to issue corporate stock therefor to an amount not exceeding $350,000. The State will not be at any expense whatever for the establishment or maintenance of the city hospital.

The Omega Upsilon Phi is the name of a fraternity established at the University of Buffalo in 1894, its membership being limited to medical students and practitioners. A chapter has recently been established in the medical department of the University of Cincinnati. The order now has chapters at the University of Buffalo, the University of Denver, the New York University, Trinity University (Toronto), and the University of Cincinnati. There are also three graduate chapters. The Grand Scribe of the order is Dr. H. J. Knickerbocker, of Wilson, N. Y.

The International Tuberculosis Congress was held at Naples last week, from the 25th to the 28th of April. It was opened at the San Carlo Theatre in the presence of the King and Queen of Italy, the Prince and Princess of Naples, the Duke of Genoa, the Premier, General Pelleux, and the minister of public instruction, Dr. Baccelli. The latter delivered the inauguration speech, and a delegate from each country represented at the congress followed. All the diplomats, including United States Ambassador Draper, attended the session.

The Board of Health of Havana, which was appointed by General Ludlow just before he left the city, has resigned, the reason alleged being that the municipal authorities pay no attention whatever to the recommendations of the board.

Philadelphia Medico-Legal Society.—At a stated meeting held April 24th, Dr. J. Madison Taylor read a paper on "Hypnotism and Some of its Medico-Legal Aspects."

Pathological Society of Philadelphia.—At the annual conversational meeting, held April 26th, Prof. Theobald Smith, of Harvard University, delivered an address entitled "Comparative Pathology and its Relations to Biology and Medicine." After the meeting a reception was tendered Professor Smith at the University Club.

Philadelphia County Medical Society.—At a stated meeting, held April 25th, Dr. Joseph Head read a paper entitled "Consanguineous Marriages," in which he contended that such unions are not in themselves necessarily harmful, but that, in general, better results are to be obtained by their avoidance. Dr. Henry Beates, Jr., read a paper entitled "Some Facts concerning Medical Education Elicited by the Application of the Law Governing Practice in the State of Pennsylvania." A discussion on "Medical Education" was then opened and participated in by Dr. W. W. Keen, Dr. H. C. Wood, Prof. John S. Stahr, president of Franklin and Marshall College; Prof. Isaac Sharpless, president of Haverford College; Professor E. D. Warfield, president of Lafayette College; Prof. W. W. Birdsall, president of Swarthmore College; Dr. John B. Roberts, James Tyson, and Martin B. Tinker. The discussion revolved principally around the question whether the fourth year of the course in a literary college should be accepted as the equivalent for the first year of a course at a medical college, and the general consensus of opinion seemed to be in the affirmative, providing that all of the work of the first year at the medical school was previously done at the literary college.

Smallpox in Winnipeg.—A despatch from Winnipeg to the New York *Times* states that smallpox is becoming epidemic in that city. Eighteen cases had been reported to the health authorities up to April 27th, and a special meeting of the city council has been held to devise means for stamping out the pest. Health Officer Inglis says the disease is of the most malignant type, and that many of the cases now in quarantine will terminate fatally. A meeting of all the doctors in the city will be called, and a house-to-house visitation made. The physicians who treated the early cases are blamed for not having recognized the disease and reported it to the authorities.

Yellow Fever in Mexico.—It is reported from Vera Cruz that several cases of yellow fever have occurred among people recently arrived there, and the fever has broken out at Salina Cruz on the Pacific coast. Unusually hot weather for this season is believed to be the cause. The fever has also appeared again at Tehuantepec, where Sir Wetman Pearson has offered the authorities a suitable site for a hospital.

American Nurses in Paris.—We are informed that in June there will be established in Paris a permanent bureau for American trained nurses, under the direction of Mrs. W. H. Booth, formerly superintendent of nurses at St. Luke's Hospital in this city. The address of the bureau will be Rue Vaugirard, No. 102, Paris, France.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 28, 1900. April 20th.—Passed Assistant Surgeon L. Morris detached from the *Brooklyn* and ordered to the *Baltimore.* Passed Assistant Surgeon J. Stoughton detached from the *Bennington* and ordered to the *Castine.* Assistant Surgeon T. M. Lippitt detached from the *Baltimore* and ordered to the *Oregon.* Assistant Surgeon J. C. Thompson detached from the *Castine* and ordered to the *Bennington.* Assistant Surgeon A. G. Grunwell detached from the *Yosemite* and ordered to the *Brooklyn.* Passed Assistant Surgeon J. F. Leys detached from the *Essex* on reporting of relief, and ordered home and to wait orders. Assistant Surgeon C. H. Delancy detached from the *Amphitrite* and ordered to the *Essex.* April 21st.—Assistant Surgeon J. C. Thompson will return to the United States by the *Bennington.* Passed Assistant Surgeon A. Farenholt will return to the United States by the *Concord.* April 23d.—Passed Assistant Surgeon M. R. Pigott detached from the Naval Academy and ordered to the *Chesapeake* same day. Assistant Surgeon K. Ohnesorg detached from the Naval Academy and ordered to the *Newport* same day.

Obituary Notes.—Dr. G. R. C. Todd, of Barnwell, S. C., died on April 28th. He formerly lived in Kentucky and was a graduate of the now extinct medical department of Transylvania University, Lexington, Ky., in the class of 1850. He was a surgeon in the Confederate army during the Civil War, and afterward settled in South Carolina. He was a brother-in-law of Abraham Lincoln.

Dr. George E. Frothingham died at his home in Detroit on April 25th. He was born in Boston in 1836, and was a graduate in medicine of the University of Michigan in the class of 1864. He was formerly a member of the faculty at that university, and enjoyed a wide reputation as an ophthalmologist.

Dr. William E. Eggert, a homœopathic physician in Santa Fé, N. M., died on April 26th at the age of seventy-six years. He was a surgeon in the Union army during the Civil War.

Dr. Charles H. Bronson, a homœopathic practitioner of Brooklyn, died on April 24th at the age of seventy-six years.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The Progress of the War.—Everything—and not least the recall of General Sir William Gatacre to England—that has occurred since my last letter points to a prolongation of the war, and the sensible person, whether Boer or Briton, is he who recognizes this and makes the fullest preparation for a winter campaign. Both in Durban and Cape Town it is pathetic to see the manner in which hot and cold fits succeed each other in influencing the public mind, while such authentic reports as come through from Pretoria—neither frequent nor full, by the way—show that the Dutch, like the English, are alternately jubilant and despondent. The ups and downs of the fortunes of war have a most marked effect upon convalescing patients. The seriously sick remain sick, of course, whoever is winning, but those who have turned the corner and are simply in hospital to regain their strength have shown themselves remarkably susceptible to the influences of hope and fear, getting better when their side wins and worse when it loses. This curious but very natural phenomenon has been frequently observed during the war, and attention has been called to it by many medical men.

Firing on Hospitals.—The British have protested in the course of the war very vigorously against what they allege to be a Boer habit of firing upon ambulance wagons and hospitals. I know that many members of the Royal Army Medical Corps implicitly believe that this has happened, and that statements to the same effect have been made by officers in the British army who would not condescend to traduce a brave foe. Still, I do not believe these enormities to have occurred. Hospitals have been hit by shells, ambulance wagons have come to similar grief, and even the laagers of women and children have been fired upon, but never of set purpose. The excitement of war increases the liability present in the minds of all men with a *parti pris,* to inaccurate observation, and I am convinced from the evidence offered by the complainants that such occurrences of the sort as are known to have happened have been simply unfortunate accidents. The Boers have throughout treated the British sick and wounded with humanity, and the offences alleged against them by some would be in contrast with their conduct in the war and their general character.

The Health of the Boer Prisoners.—The sickness on board of the transports on which the Boer prisoners are confined, though not so severe as it was at the end of March, has not yet subsided, and the population of Simonstown is apprehensive of the spread of disease from the prisoners to the town. Over one hundred Boer prisoners were down with typhoid fever in the first week in April, and deaths were still occurring daily. The prisoners receive the best medical care and attention that the British can give.

Lord Roberts' Impending Advance.—Before Lord Roberts gives the word for the next great advance toward Pretoria he will certainly make some systematic and probably successful attempts to drive back the various Boer commanders which are operating to the east of Bloemfontein and thus bring up the right wing of his force. To do this mounted men are urgently required, and the supply of horses is still very limited with the invading army; but the veterinary surgeons give a much more hopeful report on this matter than might be expected. They appear not to anticipate any great epidemics of horse-sickness, but rather believe that if the supply of remounts is regularly maintained so that the animals are not grossly overworked, the other conditions are not unfavorable to their remaining healthy. It is generally believed at headquarters that when Lord Roberts does advance his army will have its centre at Bloemfontein, its advance guard at Karll Siding (where there has recently been fighting), its right wing at Ladybrand and its left wing at Boshof. In this case the right wing will have far the most difficult ground to traverse. The sources of the Modder River will have to be crossed, and throughout the march from ridge to ridge over a succession of water-courses it will be easy for an insignificant number of Boers to hold commanding situations. Many old campaigners are hoping out loud that Lord Kitchener, who is responsible for all the transport and commissariat arrangements with Lord Roberts' army, will recognize the extreme difficulty of the eastward advance, for they think that he has asked too much of the men hitherto. Sir Redvers Bullers has recently been censured by his chief, but his men have always been well cared for; on the other hand the troops under Lord Roberts have marched and fought under the most difficult circumstances upon half-rations, while the ambulance arrangements for their wounded have been faulty. It is possible to lose as many men by treating them injudiciously as by exposing them to fire. If Lord Kitchener should give way to the feeling that to be a hard man is to be a strong man he may impede his chief's advance seriously, as well as fill the hands of the Royal Army Medical Corps to an inconvenient extent with young soldiers suffering from nothing but hunger and overexertion.

The Casualties in the British Army show sufficiently that the Royal Army Medical Corps has had an enormous lot of work to do, and the fact that with its small numbers it has been able to cope with the results of all the casualties in such a way as to win the good opinion of every one is very significant. Up to the end of the first week in April the official figures of British casualties were as follows: Officers killed, 211; officers died from wounds, 48; officers died from disease, 47; officers died from accidents, 3; non-commissioned officers and men killed, 1,960; non-commissioned officers and men died from wounds, 465; non-commissioned officers and men died from disease, 1,485; non-commissioned officers and men died from accidents, 34; total deaths, 4,253. Officers wounded, 627; non-commissioned officers and men wounded, 9,883; total wounded, 10,510. Officers missing and prisoners, 168; non-commissioned officers and men missing and prisoners, 3,722, total, 3,890. Grand total of casualties, 18,653. To these must be added 29 officers and 1,828 men who have been invalided home sick, distinct from wounded. The proportion of deaths from disease is mounting a little as the year goes on, and this must be expected, for protracted camp life has its own dangers to be added to the ordinary dangers of disease. The proportion of deaths from wounds is also going up.

Under False Pretences.—It is stated, and by this time probably the statement has been telegraphed to the United States, that the members of the Chicago Ambulance Corps have taken up arms for the Boers instead of remaining with the hospital as they were understood to be pledged to do. If this be true, there will be still greater need of British surveillance at Delagoa Bay, for such recruiting ought to be stopped. The numbers of the Chicago Ambulance Corps are not large, and the result of their step—if it has been taken—will be of no consequence, but it is to be hoped that the story will be contradicted The ambulance corps of a non-belligerent nation present at the seat of war is understood to be neutral in sentiment and inspired only by humanity. If on either side the soldiers get the idea that the ambulance arrangements are used as a mask to offensive action, they can hardly be blamed if they do not regard the Red Cross with the sanctity which perfect international arrangements should secure for it.

Plague in Cape Town.—There are five cases of plague in the quarantine station at Cape Town, but all are progressing favorably, or were by the third week in April. So far there has been no spread of the disease, and it is certainly most devoutly to be hoped that there will not be. All the larger towns of South Africa contain at the present moment double, if not quintuple, their proper population, and all the medical men, military and civil alike, have more work than they can do quite properly. An epidemic of plague under such conditions would produce a situation whose horrors will not bear pondering over.

Count Gleichen, a relative of Queen Victoria on her mother's side, was very severely wounded at the Modder River engagement, but is now back at duty. A Mauser bullet entered through the anterior margin of the right sterno-mastoid muscle behind the angle of the jaw, and emerged on the left side of the neck two inches from the middle line at the level of the sixth cervical vertebra. All important structures escaped, numbness of the palm of the left hand being practically the only symptom.

Hero-Worship Extraordinary.—Rudyard Kipling is now in Bloemfontein. He has made a tour of the hospitals, and his visits are described as being very good for the patients, who worship him, and are always immensely heartened by a few words from him. It is said that on one occasion he gave a bottle of opium to an officer, who in handing a dose to a dysenteric patient, mentioned the name of the provider. The soldier tried to keep it as a memento instead of swallowing it.

The Welsh Hospital, under the charge of Major Cockerill, R.A.M.C., left England on April 14th, and embarked on the steamship *Canada*. Several of the medical staff had already started for Africa.

Mr. Samuel Osborn, chief surgeon to the metropolitan corps of the St. John Ambulance Brigade, has gone up to Kimberly and will join Lord Roberts at Bloemfontein preparatory to the next advance. It is probable that Bloemfontein, which is an exceedingly pleasant and healthy place, will be made the site of the base hospitals which can hardly remain at Wynberg, as the lines of communication become more extended in the direction of Pretoria.

A Victoria Cross for Major Babtie, R.A.M.C.—The queen has been pleased to signify her intention to confer the coveted decoration of V.C. on Major William Babtie, C.M.G. of the Royal Army Medical Corps, for conspicuous bravery at the battle of Colenso. I have already described Major Babtie's heroism to your readers in a letter which you published in your issue of February 17th, and I then anticipated the honor for Major Babtie. The act of courage for which he was recommended for decoration is thus described in the official gazette: "At Colenso, on the 15th December, 1899, the wounded of the 14th and 66th Batteries, Royal Field Artillery, were lying in an advanced donga close in the rear of the guns without any medical officer to attend to them, and when a message was sent back asking for assistance, Major W. Babtie, R.A.M.C., rode up under a heavy rifle fire, his pony being hit three times. When he arrived at the donga, where the wounded were lying in sheltered corners, he attended to them all, going from place to place exposed to the heavy rifle fire which greeted any one who showed himself. Later on in the day, Major Babtie went out with Captain Congreve to bring in Lieutenant Roberts, who was lying wounded on the veldt. This also was under a heavy fire."

OUR LONDON LETTER.

(From our Special Correspondent)

MIDWIVES AGAIN—CHANGES IN THE BLOOD IN DISEASE—ANTHRAX—LIVERPOOL TROPICAL EXPEDITION—COLLEGES OF PHYSICIANS AND SURGEONS—DEATHS OF SIR WILLIAM PRIESTLEY, M.P., M.D., AND SIR DOUGLAS MACLAGAN, M.D.

LONDON. April 13, 1900.

THE midwives bill nearly slipped into the report stage through another accidental interference with the programme of the House of Commons. Government business included an adjournment for the Easter recess and was got through with amazing alacrity The supporters of the midwives were waiting for their chance and seemed likely to get it, when the House rather unexpectedly emptied, and a count-out ensued. It is now understood that the bill cannot come forward until Whitsuntide, but the opponents need to keep a sharp lookout for accidents. I was told the other day that the General Medical Council will meet a little earlier than usual so as to be able to see the bill as it has emerged from the committee on law. It can be of little advantage to any one for them to see it, unless they take on a degree of activity of which they have hitherto appeared incapable. Energy is required, not talk. Unless the council moves it will lose the little confidence it has retained. Some people fancy it will move for fear the expense of supervising midwives will otherwise be saddled on it. The bill will injure a good many reputations. The discussions have already done something in that way to individuals as well as public bodies.

On the 3d inst. the Pathological Society began a discussion on the changes in the blood in disease. Dr. Sidney Martin opened it with a careful paper summarizing the changes (1) in coagulability, (2) in the corpuscles, and (3) in the presence of toxic substances. Coagulation could be ascribed to the interaction of lime salts with one another and the proteids of the blood. The fibrin ferment was considered by many as a lime compound of nucleo-proteid. The changes in corpuscles affect the number of both red and white. So, too, there are changes in size and shape. The pale, watery blood of chlorosis coagulates rapidly, that of pernicious anæmia slowly. In the latter the corpuscles showed no rouleaux formation, but exhibited great variations in size and shape. The white corpuscles show greater variations in number than the red. They are increased in some infective diseases, in gas poisoning, and under the influence of quinine and salicylates. There is great increase in leukæmia, in which too myelocytes appear derived from the marrow. As to toxic agents in the blood, Dr. Martin thought their explanation lay in an auto-intoxication. Such poisons led to the formation of anti-microbic and antitoxic substances respectively.

Professor Sherrington also read a paper on the subject, in the course of which he dwelt on the great and rapid changes in the volume of the blood, such as occurred in injuries or surgical operations, especially those involving the abdominal cavity or in collapse from any cause. The reduction in volume might be enormous in the course of a few hours. The reduction fell entirely on the plasma. Hence the thirst, often distressing, after abdominal operations. The blood was inspissated and its specific gravity increased; he had seen it rise twenty degrees in a few hours. The frictional resistance of the blood would increase with this viscosity, and this would impose a heavy burden on the heart to overcome it. The gravity of such a strain on the ventricle was manifest in the algid stage of cholera. Death was often due to the inability of the heart to meet the extra demand put upon it in that stage, and a similar strain was imposed in collapse due to traumatism. The drinking of a certain quantity of fluid would then not only allay the thirst, but assist the circulation and so diminish the tendency to collapse.

After these two papers, of which only some salient points are noted above, the discussion was adjourned until the May meeting.

The Home Office has determined to give assistance to practitioners in obtaining bacteriological evidence in cases of suspected anthrax in which the infection is believed to have taken place in a factory or workshop. The directions laid down savor so much of red tape that it is to be feared the good intention may often be frustrated. The approval of the medical inspector in each case has to be sought, on receipt of which the material has to be collected and sent with a report to the bacteriologist appointed

The report of the Liverpool expedition under Major Ronald Ross is an interesting production. It contains an account of the numerous facts from which the conclusion is derived that the mosquito is a purveyor of malaria. But the term malaria is rejected by Major Ross, and so, of course, is malarial fever. Nor does he hold with paludism. Hæmamœbiasis is proposed, but I doubt if it will obtain much favor. "Gnat fever" is suggested as a popular term. and is certainly preferable, and may serve to popularize more correct notions. So, of course, the word mosquito is also rejected for the English synonym gnat.

The College of Physicians has re-elected Dr. Church as president. His address commemorated the deceased fellows of the year, according to custom. The College of Surgeons has elected two members of twenty years' standing to the fellowship, and awarded its prizes—the Jacksonian to Dr. Lambert Luck and the John Tomas prize to Mr. Mummery. Both colleges sent telegrams of congratulation to the Prince of Wales on his happy escape from assassination.

The death of Sir William Priestley was announced yesterday. He had been ill for some time, and inquiries showed that the end was approaching. He was born June 24, 1829, took his M.D. at Edinburgh in 1853, having previously joined the College of Physicians here, of which he was made a fellow in 1864, about two years after he had been appointed professor of obstetric medicine at Kings College. This position, with that of obstetric physician to the hospital, he held until in due course he retired to the consulting rank. He was physician accoucheur to the late Princess Alice and to the Princess Christian, and enjoyed for many years a large practice as a leader in his specialty. In 1893 he was knighted, and three years later was elected without opposition member of Parliament for the Universities of Edinburgh and St. Andrews. He was not a voluminous writer, but his contributions to medical literature were of value. His Lumleian lectures, "On the Pathology of Intra-Uterine Death," were printed in 1887, and he contributed articles to Reynolds' "System of Medicine" and to Allbutt's Gynæcology. In the *Annals of Natural History* for 1850 there is an account of British carices from his pen, showing that his scientific pleasure was not of a restricted character.

Edinburgh has also lost one of her foremost professors, for Sir Douglas Maclagan died on the 5th inst. "full of days," for he had reached the age of eighty-eight years, and full of honors. He made his chair of forensic medicine famous, and was consulted by the crown in many a *cause célèbre.* He was indeed the leading toxicologist for a long period. He also did much to raise the position of public health, the teaching of which was attached to his chair. He was president of the College of Physicians of Edinburgh in 1864, and in 1884 was elected to the same office in the sister college. This unusual honor from the two colleges had only once before been conferred, and that was on his father, Dr. David Maclagan, surgeon to the Queen in Scotland and physician to the forces in the Peninsular war. Sir Douglas received his knighthood in 1886. He had retired from active work for some years. Outside his professional work he was an able writer, and even indulged in poetry, his "Nugæ Canoræ Medicæ" being known to most Edinburgh men, and maintaining his reputation as a versifyer, which was as considerable as that which he possessed as a musician. In fact his general attainments were so extensive that even in a learned society like that of Edinburgh they were regarded with admiration.

THE SALICYLATES IN PNEUMONIA.

To the Editor of the Medical Record.

Sir: Since Dr. Andrew H. Smith published his article last year regarding the treatment of acute lobar pneumonia by creosote, the salicylates, etc., I have successfully treated six cases—some with salol, others with salicylate of ammonium or of sodium. If there be any preference, it is in favor of ammonium salicylate, as less irritating to the digestive apparatus. This method of treatment has great value in certain cases. I can recall several which terminated fatally in former years that I am sure would probably have been saved by this treatment. These cases tolerated large doses and made quick recoveries.

William Crawford Johnson, M.D.

Frederick, Md.

SANATORIA FOR CONSUMPTIVES.

To the Editor of the Medical Record.

Sir: In your editorial of April 21, 1900, you say in regard to sanatoria for consumptives: "But these institutions are one and all for the benefit of persons in easy circumstances. Up to quite recent times, says Dr. Goghill, writing in the *Nineteenth Century Magazine*, February, 1899, 'no attempt has been made on the European continent, and, it may be added, nor in this country, to provide like resorts for the necessitous.'"

May I call your attention to the fact that the Adirondack Cottage Sanitarium has been making such an attempt for the past sixteen years, and that its object is purely philanthropic. Although its work has apparently not come to your attention or that of Dr. Goghill, I hope it has not been without some slight influence on bringing about the recent action by the State for the care of consumptives. I enclose the fifteenth annual report.

E. L. Trudeau, M.D.

Saranac Lake, N. Y., April 21, 1900.

Lumbar Puncture in Meningism and in Sydenham's Chorea.—C. Bozzolo reports several cases of meningism and meningitis in which this procedure was resorted to, but afforded only temporary relief, the disease going on to a fatal termination. In three cases of chorea, however, it calmed restlessness and induced refreshing sleep, and restored co-ordination of movements. The symptoms of the disease returned after an interval of improvement, but repeated puncture again produced a beneficial effect. In a fourth fatal case the puncture was of no value, nor did it render any assistance to the diagnosis, as the liquid extracted was in every way normal and absolutely sterile. Cultures of the nerve substance, however, showed the staphylococcus pyogenes aureus.—*Rivista Critica di Clinica Medica*, March 31, 1900.

Medical Items.

Enzymes and Immunity.—Charles T. McClintock states that after looking over all the evidence, which is voluminous, it appears to him to be fairly well proved that the body does destroy disease germs and organisms with enzymes. As to toxins, the evidence is not so conclusive, although many facts indicate the probable truth of the enzyme explanation. The writer believes that modern investigators are pursuing the right methods and little by little are learning how the tissues combat disease-producing agents.—*Medicine*, April, 1900.

Dysmenorrhœa.—Edward E. Montgomery divides dysmenorrhœa into obstructive, congestive, inflammatory, and nervous. In the first three forms the most effective method of treatment would consist in the institution of measures with a view to the correction of the condition. Fibroids should be removed. Dilatation and curettage should be performed for obstruction and inflammatory conditions. In the neurotic cases, the rest treatment and change of scene are invaluable. Arsenic, quinine, strychnine, good diet, and large quantities of water are most advantageous in these cases.—*International Medical Magazine*, April, 1900.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 28, 1900:

		Cases.	Deaths.
	Smallpox—United States.		
Alabama, Mobile	April 14th to 21st	12	
District of Columbia, Washington	April 14th to 21st	2

BOTTINI'S OPERATION FOR THE CURE OF PROSTATIC HYPERTROPHY.

REPORTS OF CASES.

BY WILLY MEYER, M.D.,

NEW YORK,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

IN my former paper, frequently referred to, published in the MEDICAL RECORD, January 14, 1899, I have given detailed histories of the first twelve patients on whom I had performed Bottini's operation until the end of 1898. Since then, up to the time of closing the present report, April 1, 1900, I have had twelve further cases, thus making a total of twenty-four. In these Bottini's operation was done thirty times; that is to say, it was repeated in four instances (Cases I., VII., XX., and XXIII.), and done three times in one case (XIV.). In the first eleven cases a small battery without amperemeter and imported instruments were used; in the last thirteen, instruments of American manufacture and a battery with amperemeter were employed. In nine cases (IV., V., VI., VII., XII., XVI., XX., XXI., XXIV.) a cure was effected; and this could be proved to be lasting as shown by final examination made between three and twenty-five months after operation in six. Two patients did not present themselves again although requested to do so by me. Seven of my cases (I., X., XIII., XV., XVIII., XIX., XXIII.) were much improved by the operation, and this result was shown to be lasting by examination made six months to two and a quarter years after operation. Two (Cases XI., XIV.) were improved and have remained so to date, twelve and nineteen months respectively after operation. One patient (Case XI.), who was at first completely cured, to-day shows a recurrence of a number of his former symptoms, although his general condition is excellent, and the catheter has been dispensed with since the day of the operation. It must be remembered, however, that this patient was the last of the series operated upon with the help of the old battery without amperemeter, so that I am unable to say whether any of the four cuts made were carried out with the knife heated to a sufficient degree. Certainly the patient's condition is improved by the operation. Another patient, Case XIII., who also was originally cured, and considers himself so to-day, has been classed as "much improved" only, because he shows a residual urine of about thirty-three per cent. at the present time. This is the case in which the urine cleared up perfectly, but in which only one cut was made with the current at full strength. Then there were two deaths directly due to the operation (Case III., acute sepsis, and XVII., suppuration in cavum Retzii); and two deaths with Bottini's operation as the remote cause (Case IX., suprapubic cystotomy, followed by sudden death eight days after Bottini's operation; and Case XXII., phlebitis of the lower extremity followed by probable pulmonary embolism). Three patients have died since the operation was performed (Case II., six weeks after operation, of pyelo-nephritis of long standing; Case VIII., of persistent suprapubic fistula and chronic pyelitis; death, due to pyelitis, occurred three months after operation; and Case XII., a patient who was absolutely cured, urinating up to his death better than he had ever done as long as he could recall—of pernicious anæmia, nine months after operation). In other words, my cases show thirty-eight per cent. of cures (so far); twenty-nine per cent. much improved; eight per cent. improved; and a mortality of eight per cent. directly due to the operation, and eight per cent. indirectly due to the operation.

With regard to the mortality, it will be seen that death occurred equally often as the direct and indirect result of Bottini's operation. In counting deaths it is clear that if a patient, although he may have had some slight rise of temperature for many weeks or months, undergoes the operation and promptly develops a chill with high fever, to which he succumbs after a day or two; or if with the posterior incision the bladder is perforated; or if after a too deep anterior incision suppuration of the cavum Retzii with its sequelæ appears as a complication—death must, of course, be counted as directly due to the performance of Bottini's operation, at least so far as statistics are concerned.

If, on the other hand, constant vesical spasms after the operation wear out the patient, and he then asks for immediate relief, which, for special reasons, is granted—suprapubic cystotomy being done—and the patient then suddenly dies a few moments after general anæsthesia was discontinued; or if, in a patient who has been laid up for some time with an obstinate cellulitis of the hand previous to operation, a phlebitis of old varicose veins of the thigh sets in a few days after Bottini's operation, and the patient dies eight days later, although his bladder functions had been perfectly and most beautifully restored by the operation, such an occurrence certainly must be looked upon as but indirectly attributable to the operation, although, when making up our statistics, we should have to count such case among the deaths after Bottini's operation.

If, however, a man with a pyelonephritis of long standing successfully pulls through the operation, is discharged from the hospital, and then, some weeks later, develops more serious symptoms of pyelonephritis, under which he finally dies in another hospital—such a patient cannot be said to have succumbed to Bottini's operation. It would be unfair, in estimating the value and risks of the operation, to put such a case in the category of deaths due to the operation. Or, if a man who was repeatedly operated upon for prostatic enlargement by other surgeons, a man in whom vasectomy, perineal prostatectomy, suprapubic cystotomy, castration, and Bottini's operation had been successively done, and who at last carries a wide-open suprapubic fistula—I say, if such a patient submits to Bottini's operation for a second time, makes a rapid convalescence, is up and about, kept in the wards because he has no home, and dies eight to ten weeks later of an aggravation of his old trouble the pyelonephritis, such death is surely not ascribable to Bottini's operation. One might as well attribute it to the castration or prostatectomy that had been done.

In estimating the value of these personal statistics, it is but fair to bear in mind what I have said before, that these cases were not selected; they were operated upon as they came along. Had I been guided by a desire to be able to present still more favorable statistics, I should have certainly refused operation in quite a number of the twenty-four cases. I should have had fewer deaths, but also not the satisfaction of having saved the life of a patient (Case XVI.) for whom there was absolutely no help except by Bottini's operation, and in whom, besides, death would have been a real torture. It should further be borne in mind that in this series are included *all* cases so far operated upon by me; also the very first ones in which I proceeded without any personal experience. Then, too, one of the fatal issues was due directly to the anterior incision, which, as I have stated, I have since abandoned. We are, therefore, justified, I think, in expecting to reduce the mortality considerably in the future.

Before proceeding to give the full reports of my second series of cases, I shall here append a brief synopsis of the past history of my first twelve cases, together with a report of their present condition, one and a half to two and a quarter years after operation.

CASE I.—Age fifty-eight; has been suffering for one year; urinates every fifteen to thirty minutes day and night; excruciating pain when bladder is empty. Residual urine, 25:300 c.c. (1:10 oz.). Operated upon twice.

First operation, October 7, 1897; Schleich's solution No. I.; bladder empty; Bottini's original incisor used; insufficient storage battery.

Second operation, December 18, 1897. Freudenberg's modified incisor, imported small battery.

January 14, 1899 (the date of publication of my former paper), the patient was classed as "much improved."

March 26, 1900 (two and a quarter years after second operation): The patient considers himself cured; has no pain whatever; feels splendid, just as if he had never been sick; is back to work. He urinates every two to three hours during the day; nights twice or three times. Bowels in good order. He has gained more than ten pounds since the operation. When calling at my office he had urinated about an hour before; upon request he then voided 55 c.c. (about 2 oz.); residual urine 225 c.c. On irrigation the water soon returns clear. The urine is slightly turbid; acid. Prostate per rectum is hard; its upper border can be reached; length of urethra, 20 cm. He still refuses a third operation, which was advised fifteen months ago.

CASE II.—Age seventy-three; patient in desperate condition; chronic pyelo-nephritis. Operation December 23, 1897. No improvement. He died six weeks later, in spite of operation.

CASE III.—Age sixty-four; bilateral pyelitis, chronic sepsis. Death from acute sepsis, thirty hours after operation.

CASE IV.—Age sixty-four; his trouble started seven years ago, but has become much worse within the last four years; he urinates three to six times during the night, oftener in the daytime. Incomplete retention; he uses catheter three times in twenty-four hours. Chronic cystitis; kidneys free. Residual urine, 10:200 c.c. ($\frac{1}{3}$:6$\frac{2}{3}$ oz.).

Operation February 26, 1898, under eucaine anæsthesia; bladder empty; three cuts, posterior, left lateral lobe, anterior. Freudenberg's incisor; small battery.

November 18, 1898: Frequency of micturition three to four times during the day, nights once; no pain whatsoever. He has gained in weight. He voids 150 c.c. (5 oz.) in a good stream; 300 c.c. injected are passed up to the last drop. There is some cystitis. Catheter dispensed with since operation.

Last examination January 4, 1899: the same good result.

With my request of March, 1900, to present himself at my office for examination, the patient failed to comply.

CASE V.—Age fifty-nine. There has been increasing frequency of micturition for the last four years, which has become much aggravated since two years. There is incomplete retention; some incontinence. He urinates every half-hour to hour day and night; much pain; frequent catheterization; chronic cystitis; no kidney lesion; residual urine, 150–180 c.c.

March 28, 1898, Bottini's operation; eucaine anæsthesia; bladder empty; two cuts, one posteriorly, the other through projecting growth in posterior urethra. Incisor; small battery.

October 18, 1898: He urinates once every six hours; at times slight incontinence. Catheter not used since operation. No pain. He has gained in weight.

March 24, 1900 (written communication); Two years after operation: "urinates three to four times during the day; sleeps through the night; general condition, 'tip-top'; catheter never used again; passes normal quantity of water; urine absolutely clear; stream good; no pain; is relieved as far as his bladder trouble is concerned."

CASE VI.—Age fifty-two; incomplete retention; urinates every fifteen to thirty minutes in the day-time; nights every hour to hour and a half; much pain; catheter not used; cystitis; pyelitis surely present; residual urine 150:175 c.c.

Operation May 7, 1898: Eucaine anæsthesia; bladder filled with 150 c.c. (5 oz.) sterilized boric-acid solution;[1] three incisions, one posteriorly and one through each lateral lobe. Incisor; small battery.

October 24, 1898: Urinates four to six times in twenty-four hours; no pain; has gained in weight. Residual urine, 325–75. Of 350 c.c. (about 12 oz.) every drop is passed with two short intermissions; no sign of cystitis or pyelitis; urine cleared up completely.

Final examination March 29, 1900 (twenty-three months after operation): Urinates three to four times during the day, nights once; no pain; urine passes in a forcible, good stream; toward the end he has to strain. He emptied his bladder about one and a half hours ago. He now passes 150 c.c. of beautifully clear urine; residual urine 50 c.c. Of 200 c.c. nitrate-of-silver solution, 1:5,000, injected, every drop is passed. The patient states that he sometimes voids more than 12 oz. at a time. He has gained considerably in weight and feels excellent; is steadily at work.

CASE VII.—Age sixty-eight. His suffering dates back nearly one and three-quarter years. Incomplete retention; he urinates every fifteen to sixty minutes during the day; twice in the latter part of the night, always with pain; has been using the catheter once or twice a day for the last fifteen months, always before retiring; chronic cystitis; no renal lesion. Residual urine, 30:300 c.c.

Operation June 8, 1898: Eucaine; three cuts, one backward and one through each lateral lobe. Incisor; small battery.

September 29, 1898: Empties his bladder every three or four hours during the day, nights once; no pain. General condition improved; no residual urine; urine still slightly turbid; catheter laid aside.

Last report (in writing), March 24, 1900 (one and three-quarter years after operation): Has gained seven pounds since operation. He urinates five times during the day, nights not at all. Quantity in twenty-four hours 1,500–1,600 c.c. (50–53 oz.). To use the patient's own words in response to my queries: "The stream gives me entire satisfaction. General condition is first-class in every respect; my health is fine since the operation; I feel now that life is worth living."

---

[1] From this time on I have done all my operations with the bladder filled, as in this case.

Case VIII.—Age sixty-eight. The following operations were done by other surgeons before he came to me: Ligation of both vasa deferentia; six months later, removal of left half of prostate through perineum; fifteen months later suprapubic cystotomy. One week later, bilateral orchidectomy; seven weeks later, on May 12, 1898, Bottini's operation. He has persistent suprapubic fistula. He then, by request of the former attending surgeon, was placed under my care.

June 11, 1898: Second Bottini operation, done by me. First result good; greater part of urine passed through normal channel; later, fistula opens again. Patient kept in hospital. August 25, 1898, patient died under symptoms of septic pyelitis (report of house surgeon, who had taken charge of the case during my absence from the city).

Case IX.—Age sixty-four; he has been having bladder trouble for the last nine years. Incomplete retention; a great deal of pain; catheterizes himself three times in twenty-four hours; cystitis; quiescent chronic nephritis; no pyelitis. Residual urine 30: 300 c.c. (1 : 10 oz.).

June 15, 1898: Operation; eucaine anæsthesia; three incisions, one posteriorly, one through each lateral lobe. Six hours later chill with rise of pulse and temperature. Slow improvement. Kiss' instrument; small battery had been used. June 23d, suprapubic cystotomy on account of continuous spasm. Patient died a few minutes after having reached his bed. No post-mortem.

Case X.—Age sixty-six; incomplete retention; frequency of urination every ten to sixty minutes during the day; three to five times in course of the night; calls very sudden; wears urinal; chronic cystitis; no kidney affection. Residual urine, 30: 30 c.c. Bladder scarcely holds 90 c.c. (3 oz.).

Operation June 22, 1898: Eucaine; three cuts; posterior, through right lateral lobe, and anterior. Kiss' incisor; small battery.

October 31, 1898: Urinates in a strong stream without pain, every two or three hours during the day, night three times; has gained in weight. While at my office he passed 85 c.c. (3 oz.), residual 10 c.c. (⅓ oz.). On irrigation, the water soon returns clear. Of 100 c.c. injected, every drop is passed; urinal put aside three weeks after operation.

Patient has not presented himself for examination, so far.

Case XI.—Age sixty-two; trouble for the last five years; incomplete retention which becomes complete now and then. Micturition every twenty to thirty minutes during the day; half-hourly during the night, very painful. Catheter is used three times in twenty-four hours. Chronic cystitis; slight pyelitis; residual urine 100: 50 c.c.

Operation September 22, 1898: Four cuts; local anæsthesia. Incisor (Kiss), small battery. Difficulty experienced in removing instrument. When at last withdrawn, it is found that the knife, in re-entering the groove of the female part, has become bent sideways at an angle of fully 45°.

November 11, 1898: Urinates six times during the day; nights three or four times; total amount about 2,000 c.c. (70 oz.). Vesical capacity 360 c.c. (12 oz.); stream excellent; not a particle of residual urine. Patient looks well; has gained in weight; catheter has been laid aside.

November 3, 1899: Urinates more frequently—five to six times nights; every one or two hours during the day; stream less forcible; largest amount voided at one time 150–180 c.c. (5–6 oz.). Upon request urinates 150 c.c. (5 oz.); residual urine not quite 50 c.c. Slight cystitis. Of 250 c.c. of boric solution injected 175 c.c. are passed, leaving a residual urine of 75 c.c. Prostate large and hard.

Final examination, April 13, 1900: The patient reports that he urinates every one to two hours during the day; nights three to five times; has no strain. When calling he had urinated over three hours ago; he passes 200 c.c.; residual urine 20 c.c.; of 250 c.c. of boric-acid solution injected, 175 are voided. He states that he is subject to colds, when his condition is always worse. He looks well, has gained in weight; bowels normal. Does not take medicine of any kind; has not used catheter since operation. His general condition is splendid. In view of the change that has taken place since the operation, this case, which was originally classed as cured, will now have to be relegated to the "improved" cases.

Case XII.—Age fifty-two; increased frequency of urination since the last six weeks; nights five to six times; often during the day; has had poor stream all his life; urine passes in drops, has to strain a good deal; pains in glans. Residual urine 30 : 100 c.c. (1 to about 3 oz.); is intensely anæmic, has lost fifteen pounds within last nine months.

Operation October 4, 1898: Four cuts; incisor and storage-battery of American make.

October 30, 1898: He empties his bladder two to three times during the day; nights once or twice; does not remember ever having had a better stream of urine than at present.

Some time after his discharge from the hospital, the patient came under the care of a colleague, who kindly furnished me with the following notes:

"Mr. I—— continued to suffer from an intense anæmia with very irregular temperature, the same rising later as high as 106° F. at times. He had the same symptoms until his death on March 6, 1899, save occasional periods of delirium. Blood examination showed no plasmodium malariæ, no increase in white blood corpuscles, no change in size of red blood cells, no free pigment. The blood culture made at the time of the autopsy also proved negative. Post mortem revealed absolutely nothing save an intense anæmia of the entire system. During the remainder of his life he had absolutely no symptoms referable to either bladder or kidney. He frequently remarked on the great ease with which he could pass his urine. Urinary examination was also negative."

Case XIII.—J. S——, forty-seven years of age; married; had been suffering from bladder trouble for the last two years. Micturition had become more frequent and required straining. There was pain before, during, and after the act; also some after-dribbling. The urine appeared clear. Two months after the onset of these symptoms the patient consulted his family physician, who pursued internal treatment. Another physician was consulted, who introduced a sound and diagnosed prostatic enlargement. Then some hæmaturia appeared; the pains increased and also the frequency of micturition. The patient saw another physician still, who found residual urine, advised him to use a catheter at night, and employed irrigation for the catarrh that had meanwhile appeared. Dissatisfied with his condition, the patient called on a fourth doctor, who suggested bilateral castration as the only means of curing the trouble; if not accepted, the use of the catheter, which, it was added, he would probably not be able to discard for the remainder of his life. The patient thereupon continued treating himself for about a year, becoming much reduced in general health. The thought of what he considered his fate, to use the catheter for the remainder of his comparatively young life, or submit to emasculation, greatly depressed him.

At this stage the patient was referred to me by a colleague, that I might determine whether Bottini's operation would be advisable. He called on November 5, 1898. At that time he urinated under a good deal of burning pain, every half-hour to hour during the day; six to seven times during the night. He used the catheter regularly every evening before retiring and also irrigated his bladder. He stated that he had had a chill five months ago, followed by fever; the latter was of short duration, however. Complete retention had never occurred. He urinated, voluntarily, 75 c.c. of a turbid urine; residual urine 80 c.c. It took some time before the bladder was cleaned out, so that the water returned clear. Of 150 c.c. injected, the patient was able to pass not quite 100 c.c. in a fine stream. His prostate appeared much enlarged per rectum; its upper portion could be just reached by the tip of the finger.

Report on urinary examination: chronic cystitis, kidneys not involved.

November 8th, cystoscopy: Pathognomonic groove at vesical neck nicely developed; both lateral lobes equally enlarged; post-prostatic pouch and trabecular bladder well marked; no stone.

November 11th, Bottini's operation: The new storage battery with amperemeter was again used. According to advice given, it had been charged for eight hours with two fifty-candle-power lamps. Four incisions were contemplated; however, the posterior cut only could be carried out with the full strength of the current; on the return trip of the knife through the right lateral lobe, which was next divided at an angle of 45°, the needle dropped ten points; the two other cuts then were omitted. A like accident will not happen to me again. We have since found a way of charging the battery in such a manner that it can be absolutely relied upon for the full strength of current during the entire operation. (See above.) Besides, I superintend the charging personally.

The day following the operation the patient micturated much more easily than before; then absolute retention set in, accompanied by a slight rise of temperature, 101.6° F., but no chill. Regular catheterization became necessary and was performed every eight hours. To avoid the pain that was caused by the introduction and removal of the catheter, it was left in permanently on the third day and not removed until six days later. From that time on improvement was noted and the capacity of the bladder gradually increased. The patient was given urotropin and strychnine, also salol; no vesical irrigation was done.

On December 6th, the bladder holds 16 ounces at a time, which is voided in one single act. He urinates 74 to 96 ounces within twenty-four hours, with little pain and at regular intervals of two to three hours, night and day. The stream is full and strong up to the last. He had urinated last at 8 o'clock in the morning with his stool, and had retained his urine until 12 M., when he passed 575 c.c. in a good continuous stream, with the normal jerks at the end. The catheter then introduced found 70 c.c. of residual urine; 250 c.c. of a two-per-cent. boric-acid solution thereupon injected is passed to the very mark of the graduated glass. The urine was still slightly turbid. The patient was told to continue urotropin and strychnine three times a day and to reduce the quantity of liquids ingested.

When seen again, on December 17th, he stated that he urinated seven to eight times in twenty-four hours; nights once. At the time of the nocturnal micturition 17 to 18 ounces is passed in a good stream, and without pain. The catheter has not been used again since the operation. The patient urinates 250 c.c. in a good stream; the catheter introduced about three minutes later finds 5 c.c. of residual urine. On irrigation the water soon returns clear. His general condition is much improved, and he has gained in weight.

Under date of December 31st, the record says: The patient is doing nicely. He urinates six to seven times in twenty-four hours; nights once or not at all. Average capacity of the bladder, 15 ounces; there is no pain. He had urinated at 8 in the morning, and when calling at my office at 9, passed 50 c.c. The catheter then introduced does not find a drop of residual urine in the bladder. Of 300 c.c. injected, 280 c.c. is passed. The patient stated that he thought, if he had tried, he could have probably passed the entire amount. He has returned to business and works hard all day.

February 18, 1899: The patient feels splendid and has gained considerably in weight. He urinates four times during the day, nights once or not at all, and is entirely free from pain. He does not have sudden calls for micturition. He urinates 300 c.c. in one good continuous stream with normal jerks toward the end. The urine is absolutely clear. The catheter immediately introduced does not find a drop of residual urine; 200 c.c. of the two-per-cent. boric-acid solution then injected are passed up to the mark of the graduated glass.

June 3d: Everything is in the best of order. He urinates three or four times during the day; nights once or not at all.

November 27, 1899: The same good condition prevails. He urinates four or five times during the day in a good stream; nights twice. When calling at my office, had just urinated. He passed 75 c.c. Residual urine found, 10 c.c. Of 250 c.c. then injected, every drop is voided in a good stream.

March 29, 1900 (one year and four months after the operation): Patient feels well; he urinates five or six times during the day, nights once; no pain; good stream. While at my office, having urinated three hours ago, he passed 500 c.c. of absolutely clear urine; residual urine 250 c.c. Of 300 c.c. (10 oz.) of nitrate-of-silver solution, 1 : 5,000, 200 are passed. Patient has gained considerable in weight; considers himself cured; bowels normal; catheter no longer used.

This case very nicely illustrates that the posterior cut alone, if properly carried out, may sometimes be sufficient to relieve the patient. Nevertheless, no conclusion should be drawn from such a single case, but the rule of making one posterior incision at the median line, and one each through the two lateral lobes, should be followed. I feel confident that the originally achieved ideal result would have continued had all three incisions been done with equal thoroughness. I intend to propose a second operation if the amount of residual urine should increase.

CASE XIV.—H. J——, seventy-one years of age. Eighteen years ago retention set in for the first time, but ceased after one week's use of the catheter. During the last fourteen years he has recurring desire to urinate when walking down-stairs. There is gradually increasing frequency of micturition. He has had diabetes for fifteen years, with varying quantities of sugar, and is also suffering from constipation. The patient went to Wildungen to take the baths in 1892, where the doctor advised him to use the catheter twice a day on account of his prostatic enlargement and vesical catarrh. Since then he has used the catheter twice daily and never urinated a drop voluntarily. He has never had a chill or pains in the lumbar region. After the use of the catheter there has frequently been some discharge of blood. Lately the trouble has become much aggravated; he has to use the catheter every three or six hours; nights rarely less than twice. He requires the longest catheter in the market, one that measures fifteen inches (38 cm.) from tip to eye. Recently the meatus has become inflamed and infiltrated, which produced a stenosis. Since then his condition had become much more troublesome. When calling at my office on January 9th, 1899, he stated that it had been impossible for the last twenty-four hours to introduce the web catheter, always used thus far. I found the prostate very large and hard; its upper border could not be reached with the finger. I succeeded in introducing a Trendelenburg prostatic catheter sound (No. 14) a description of which was first published by me in the *New York Medical Journal* for August 6, 1892, and relieved the retention. January 11, 1899, the patient was admitted to the German Hospital, where meatotomy was performed, and after that catheterization was regularly carried out.

January 23d, cystoscopy: Great difficulty was experienced in introducing the instrument. The condition found was: a large median lobe; right lateral lobe larger than the left; sacculated bladder. The examination was followed by a hemorrhage, which, however, was not alarming.

Bottini's operation was performed on January 25th, with the bladder filled with 200 c.c. of sterile boric-acid solution. When the introduction of the incisor, after two unsuccessful attempts, was finally accomplished, the beak of the instrument well hugging the prostate, the latter's tip could be palpated about four and a half inches (11.5 cm.) above the sphincter and muscle. Four incisions were made, the posterior one 4 cm. in length; the one through the right lateral lobe at an angle of 45°, 4 cm., the one through the left lateral lobe at 90°, 3.5 cm., and the anterior cut with the handle of the instrument depressed, 2 cm. long. The patient was unable to urinate just after the operation; there was no general disturbance, although he suffered much from vesical and rectal tenesmus. Catheterization being difficult, the permanent catheter was introduced and left in place for five days. On February 20th, the patient was still unable to urinate voluntarily, but catheterism was certainly much easier. He soon left his bed.

On February 21st, a second Bottini operation was performed. Introduction of the incisor was markedly easier; again four incisions of same length as those at the first operation were made. There is no general disturbance, but voluntary micturition does not begin. On the twenty-sixth day following this operation, on March 19th, after the discharge of exceedingly large eschars, the patient passed water voluntarily for the first time within the last six and a half years, first in small quantities, which, however, rapidly increased.

On March 28th he urinated 50 c.c. without having the desire. The catheter found 500 c.c. residual urine. A Nélaton catheter passed with the greatest ease and the irrigation water promptly returned clear.

Upon reflecting on my failure, thus far, in relieving the patient of the greater amount of residual urine, I sorely felt, for the first time during my work on the prostate with Bottini's operation, the need of an instrument that permitted of making incisions longer than 4 cm., this being the limit of the one then in my possession. I therefore had constructed for me an incisor allowing of an incision 8 cm. in length.

As soon as the instrument was completed, I proposed a third operation to the patient, to which he readily acceded. It was done on April 4th. On firmly hugging the prostate the beak, to my dismay, suddenly slipped into a distinct groove, an accident which naturally frustrated my plan of reducing the urethra to 21 cm., since I could not know how many centimetres the instrument had slipped forward. Under the circumstances I contented myself with a posterior cut of 3½ cm., one through the right lateral lobe at 45°, of same length, and one through the left at 90°, 2 cm. long. There was absolutely no reaction; the permanent catheter introduced immediately after the operation was left in place for three days. After its removal the patient was regularly catheterized twice to three times a day, first with Mercier's, then with Nélaton's soft-rubber catheter. Commencing with the eleventh day, large escharotic pieces were discharged.

The patient soon began to urinate spontaneously, using the catheter only before retiring. Average amount of residual urine 500–600 c.c.

On April 27th he urinated every one to two hours, day and night. Spontaneous micturition at office upon request, without inclination, gave 50 c.c., residual urine 450 c.c. Nélaton catheter entered with greatest ease. Irrigating water returned clear after the first washing. Of 500 c.c. injected, only 100 could be passed.

May 13: Diabetes has become aggravated (eight per cent.). Average amount of urine in twenty-four hours over four quarts. On June 30th, under proper treatment, the amount has been reduced to 1,060 c.c. in twenty-four hours. He uses catheter only once; feels comfortable; urinates spontaneously four to five times during the day and about the same number of times during the night. Largest amount of urine passed in one act 180 c.c., residual urine 530 c.c.

October 10th: Length of urethra 25½ cm. (10 inches). Amount of urine voided in twenty-four hours, 1,500 c.c. He irrigates his bladder every morning. Residual urine, 400–500 c.c. He has no desire to pass water after that for eight or ten hours. Greatest amount voided at one time, 80–100 c.c. His bowels move regularly, and his general condition is much improved.

December 26th: He urinates spontaneously between 1,100 and 1,150 c.c. at irregular intervals within twenty-four hours. He has no pain and is not annoyed by a frequent desire to urinate. Residual urine always between 600–650 c.c. He enjoys good rest during the night without the call to rise. Largest quantity of urine passed spontaneously, 150 c.c. The call is never urgent; he can retain the urine sometimes for longer than two hours. The patient considers himself very much improved.

Final examination April 4, 1900: Quantity of urine passed in twenty-four hours 2,400 c.c. (80 oz.); greatest amount voluntarily voided at one time 150–250 c.c. He catheterizes himself twice daily, after which he has rest for seven to eight hours. Residual urine between 500 and 700 c.c. No irritation at neck of bladder; he is able to retain; bowels normal; marked gain in weight. He is well satisfied with his present condition.

In reviewing this case, I cannot help thinking, as mentioned before, that a far more favorable result could have been obtained at the time of the first operation, had I been in possession of an instrument so constructed as to permit me to make the incisions long enough to cut through the prostate in its entire length and thus to reduce the urethra to its normal length. "Insufficient length of the incisions," then, is evidently the cause of the imperfect result in this instance. There can be no doubt that this would have been a fit case for prostatectomy, had not the very marked diabetes and the senile condition of the patient presented an absolute contraindication to such an interference. With my present knowledge, I feel convinced I should achieve a better result in a similar case with a large fibrous prostate. As indicated above, I should compare the length of the urethra with the measurement of the prostate per rectum just before the beginning of the operation, and make my incision to correspond to this difference if not to exceed it by 1 cm. I also would slowly go over the same route with the galvano-caustic knife twice in immediate succession.

Case XV.—J. H——, seventy-eight years of age. Nine years ago he had first complete retention. He was first seen by me in 1896. He then had to rise three to six times during the night, and urinated every two hours during the day under considerable straining. There was slight after-dribbling; residual urine 50–60 c.c. The prostate was very large. He was then comparatively well for the following three years. I saw the patient again on December 29, 1898, when he complained of intermittent complete retention, the last onset having occurred December 26th; the one previous to that five to six months ago. He has his bladder washed out about twice a week; otherwise the catheter is not used. His condition has become much worse during the last few weeks, especially as regards frequency of micturition. His nights' rest has been greatly disturbed, the call coming eight to ten times. There is slight epididymitis. He urinates 35 c.c., residual urine 25 c.c., turbid. The bladder holds not quite 200 c.c. Prostate palpated per rectum is very large; its upper border can just be reached; it is somewhat tender and compressible. Treatment: regular irrigation, increasing doses of salol; urotropin.

January 12, 1899: His condition has improved; micturition less troublesome. There is no pain. Micturition, nights four to five times; during the day about every two hours. He urinates 90 c.c.; residual urine. 100 c.c.

January 29th: Cystoscopy; introduction of instrument very difficult. In passing the prostate the beak distinctly slides over a very irregular surface; there is hemorrhage, which necessitates change of water in bladder. There is a large median lobe; the right lateral lobe distinctly projects into the lumen of the bladder; left lateral lobe smaller. Complete retention follows examination, but is relieved by silver catheter with large curve. The patient remained in bed for five days, after which the same condition as before cystoscopy prevailed.

February 11th: Bottini's operation was performed at the German Hospital, four incisions being made: posterior, 3½ cm. through right lateral lobe at an angle of 45°, through left lateral lobe at 90°, of same length; anterior incision, 2 cm. The bladder had been filled with 150 c.c. of sterilized boric-acid solution. Reactive swelling of gland was very marked. Retention set in; catheterization was very difficult; relief was obtained by Trendelenburg's prostatic catheter sound.

February 12th (thirty hours after operation): Rise of temperature up to 103° F., with corresponding pulse. Both slowly subsided in the course of a few days.

February 13th: Introduction of soft-rubber catheter on metal guide was successful; it was left in place for six days; after that regular catheterization, which became gradually easier. The patient commenced to urinate spontaneously on the 22d of February. Vesical irrigation was carried out twice daily. He left the hospital on March 15th.

March 20th: He can retain urine for fully three hours; micturates three or four times during night in a good strong stream, without pain. When calling at my office he had passed his water an hour and a quarter previously and had no desire to urinate; on request, however, he passed 90 c.c.; residual urine was withdrawn by Mercier catheter, which entered without difficulty after a Nélaton had refused to pass, 30 c.c. Catarrh is still marked. Of 250 c.c. of boric-acid solution then injected, 210 c.c. are passed. Medication, urotropin and strychnine.

March 27th: Frequency of micturition during the day is every three hours; nights three to four times without pain. In comparing his former condition with the present the patient states as follows: Formerly there was a burning sensation during micturition; long waiting before the water would appear; no stream. Now, the burning sensation is very slight; he does not have to wait, and water passes in a good stream. He had not urinated for two and a half hours before calling, and then passed 175 c.c. in a good long stream; residual urine, 75 c.c. Vesical catarrh was still marked. Of 250 c.c. injected, 40 c.c. were retained. Continued regular irrigation of bladder with nitrate of silver was ordered.

May 1st: He urinates every two or three hours, nights two to three times, retains easily 250–270 c.c. He passed about 120 c.c. three hours ago; now 175 c.c., residual urine 50 c.c. Length of urethra, 24 cm.

June 8th: The patient feels splendid, has no pain and no annoyance. Of 200 c.c. injected, 150 are passed, leaving a residual urine of 50 c.c. The patient is perfectly satisfied with his condition and would consider himself cured, if frequency of urination could be still somewhat reduced and if he did not see that his urine is still slightly turbid. He has gained considerably in weight.

Final examination March 27, 1900 (thirteen months after the operation): Patient urinates every two or three hours daily; nights four or five times; no pain; stream much better than before operation. He has no desire to micturate, but on request passes 55 c.c. (nearly 2 oz.), residual urine 80 c.c. (2⅔ oz.). Very slight cystitis; irrigation water returns clear at once. Of 180 c.c. 100 are passed. Length of urethra is 23 cm. Prostate is of medium consistency; its upper border cannot be reached; catheter has not been used since he was discharged from after-treatment at the time of the operation. The patient—although the father of three doctors—is absolutely opposed to taking any medicine internally; therefore, he also refuses urotropin. He has no pain; would consider himself entirely well if he urinated less frequently.

This case certainly belongs to the class of "much improved." As stated, the length of his urethra still measures 23 cm. Here too, therefore, the insufficient length of the incisions was the reason that perfect urinary drainage was not established by the interference. I suggested to the patient that he have a second operation performed. This, however, he refused, stating that he is entirely satisfied with his present state.

Case XVI.—M. M——, fifty-eight years old; has had urinary trouble for the last three or four years. A year ago he urinated every two hours during the day; four or five times at night, with considerable pain in urethra; some tenesmus; no lumbar pains; no chills. He has been treated with medicine. There was steady aggravation of all symptoms, until, about two weeks ago, he had to urinate every three or four minutes during the night and every fifteen minutes during the day. Absolute retention; overflow; regular catheterization. He now catheterizes himself four or five times during the day. On December 18th there was hæmaturia for the first time, following the intravesical interference.

The patient called at my office for the first time on December 19, 1898. He was unable to urinate spontaneously, having drawn off his water in the morning before leaving home. Nélaton catheter withdraws 625 c.c. There is a good deal of catarrh. The prostate is large and soft. The patient is very weak and extremely emaciated. Pulse is irregular, about 122; temperature, 103.6° F.

Urinary analysis: Chronic cystitis with alkaline fermentation; renal hyperæmia or possibly a more marked renal lesion, but no pyelitis. It is not easy to make a definite diagnosis, as it is difficult to account for the continuous fever. The lungs are not affected; there is no tuberculous family history; there are no symptoms of typhoid. Blood test for plasmodium and Vidal negative. With regard to malaria it is not absolutely reliable, since quinine had been given before. His temperature is reduced after about one week's time by the continuous use of methyl blue and quinine.

December 23d: Resection of the vas deferens was done on both sides. No particular improvement was noticed during the following two weeks. Overflow as before. Regular catheterization. The bladder contains never less that 480 c.c. (16 oz.).

January 4, 1899: Cystoscopy. Some difficulty is encountered at the neck of bladder when the instrument is introduced. Marked trabecular bladder; deep characteristic groove at the internal fold. Left lateral lobe larger than right; there is no median lobe; no stone. Internal medication of methyl blue is continued.

January 6th: Bottini's operation. After repeated attempts, the incisor enters the bladder. On hugging the prostate with the beak the rectal diameter of the same seems alarmingly reduced. Had not all the characteristic symptoms been seen, everybody would have doubted the presence of prostatic enlargement. Not knowing exactly what best to do under the circumstances, but eager to get through with one operation, the posterior cut was made 3½ cm. long; the one through the left lateral lobe at an angle of 45°, and the one through the right lateral lobe at 90°, 3 cm. each. The anterior cut was omitted, because in the attempt at turning the beak toward the symphysis, the instrument suddenly slipped out of the bladder. When removed, much thoroughly burned prostatic tissue was seen to adhere to the knife. Immediately after the operation the patient complained of a great deal of pain and had some rectal tenesmus. A few drops of urine were passed per urethram; there was much pain in perineum. At 6 P.M., temperature, 104° F.; pulse, 116. Attempt at entering the bladder with a catheter was unsuccessful, although the instrument could be introduced pretty far. Another effort at 9 P.M. met with the same result. The patient felt an urgent desire to empty the viscus; therefore, aspiration was done above the pubes, about 600 c.c. being drawn off. From hour to hour there was continually increasing swelling of the right part of the scrotum, extending up to the right inguinal canal. Diagnosis: perforation of urethra; urinary infiltration. Operation at 11 P.M. (fourteen hours after Bottini's operation) under superficial general anæsthesia. Multiple incisions were made in scrotum; the subcutaneous tissue was thoroughly infiltrated and blue (methyl blue). Burnt shreds of tissue were found in the median incision just above the anus; the urethra here was perforated. Introduction of tube from perineum into bladder was unsuccessful. Drainage of scrotal wounds; moist dressing.

January 10th: Temperature almost normal; pulse still slightly elevated. Since the last operation, the patient has emptied his bladder through the perineal wound in short, frequent intervals, over which he has no control, except that he feels the desire to urinate. He rests on a rubber air bed-pan. With the help of very careful nursing, I succeeded, to my delight, in saving this patient's life. For a long time his pulse ranged around 120; the rectal temperature never rising above 100° F. On February 15th his pulse for the first time fell to 96, his temperature being about as usual, 98.4° F.

March 3d: Pulse 88. His condition now slowly improved. He left his bed at the end of February and by the middle of March was able to walk around. Meanwhile the perineal wound had slowly contracted so that, on March 15th, not quite ten weeks after the operation, he urinated spontaneously for the first time in the normal way, about two ounces. On March 22d the report states that he urinates every hour to hour and a quarter, about 120 c.c. (4 oz.) at a time, 30 c.c. (1 oz.) still passing through the wound. On March 28th he weighed one hundred pounds.

April 2d: The patient urinates every two to two and a half hours.

April 3d: Weight one hundred and one-half pounds.

April 7th: A typical attack of gall-stone colic set in, with a pulse of 128; temperature, 103° F., which, however, slowly yielded under proper treatment, so that everything is normal again on April 9th. On April 10th he left for his home in the northern part of this State, accompanied by his faithful nurse. The perineal wound had completely closed; he urinated every two or three hours in a satisfactory stream, without pain. The catheter had been laid aside since the operation.

March 16, 1900 (fourteen months after the operation): The patient reports that he urinates every hour during the day; nights seven or eight times; the stream is satisfactory; the perineal fistula has remained closed; he has gained in weight; the bowels are normal. He has had no local treatment since he left my care.

It will be readily understood that the experience I had with this patient immediately after the operation greatly embarrassed me, although the final result was most gratifying. It is plain that the too great length of the cuts here produced the perforation of the urethra. As stated before, I did an unintentional internal perineal urethrotomy. I believe and hope that, with my present experience, such an accident will not happen again. I had, up to that time, never made the posterior cut shorter than 3 to 3½ cm., neither had I encountered a gland of such sponge-like compressibility as this one. It was, furthermore, imperative that the obstruction be relieved without delay, lest the life of the patient, who was greatly reduced, should be lost. I believe that an incision of 1 to 1½ cm. in length would have been ample in this case, and, most probably, would have effected a cure with less distress to the patient.

In this particular instance Bottini's operation not only entirely relieved the patient, but directly saved his life. Any colleague, seeing the patient at the time I undertook the treatment, would have agreed with me that he was nearly dying. It was only on account of the intense suffering of the man, night and day, that I was induced to try Bottini's operation.

CASE XVII.—H. U——, seventy-nine years old, well preserved; absolute retention of urine for the last twenty-two years. In the beginning he used the catheter once a day; later twice, then three times, and up to about a year ago every six hours. At that time he had a severe hæmaturia. Since then the call to urinate has become rapidly more frequent, so that now he is obliged to use the catheter every hour to hour and a half, day and night; introduction of the instrument at times is very painful. Amount of urine discharged, about three quarts in twenty-four hours. On March 23, 1899, when calling at my office, 200 c.c. of urine were drawn off by means of a soft-rubber catheter which entered the bladder without difficulty. The latter did not prove irritable on irrigation. On rectal palpation the prostate was found to be soft, the right lateral lobe being larger than the left. He has prostatorrhœa. Length of urethra, 23 cm.

Urinary analysis: Chronic pyelo-nephritis; chronic cystitis with alkaline fermentation.

Cystoscopy shows the characteristic groove pointing obliquely toward the right of the patient. The right lateral lobe does not appear very large in the picture; toward the median line a perpendicularly rising mass is distinguished, evidently a large median lobe; marked trabecular bladder. Toward the right lateral vesical wall there is a dark yellowish spot, about the size of an almond, the meaning of which cannot be distinctly determined. Sudden pressure repeated at short intervals on the suprapubic region of the patient does not alter its position. Drawing off the liquid in the bladder and forcibly injecting new fluid through that tube of the irrigating cystoscope which ends with a wide opening at the lower end of the shank to the side of the prism, does not move it either. The examination is much interfered with by a continuous hemorrhage from the prostate, which at once destroys the transparency of the injected fluid. A superficial ulceration, its surface covered with adherent mucus, is suspected. Doubt as to the correctness of this assumption is entertained, however, on account of the fact that mucus covering vesical ulcers generally appears white on cystoscopic examination, and not yellowish.

March 31st: Bottini's operation. After the incisor has been introduced, and turned around its axis for 180°, its handle cannot be well raised; the tip cannot be felt with the finger in the rectum. Conclusion: The middle lobe has been turned down and backward. On pulling the incisor firmly forward, the beak suddenly slips forward and toward the right of the patient into a groove; its tip can then be reached per rectum. It evidently rested in the deep groove between the right lateral and middle lobe of the gland. Posterior incision as well as that through right lateral lobe at an angle of 45° and through left lateral lobe at 90°, 4 cm. long. Before carrying out the anterior incision, which is made 2 cm. long, the handle of the instrument is well pressed down, so that such prostatic tissue as might possibly press down and backward the posterior part of the urethra should be thoroughly divided. There is profuse hemorrhage. Immediate introduction of a Mercier catheter is impossible.

Seven hours after operation the temperature rises to 102° F.; pulse, 88.

April 1st: Temperature not exceeding 101.6° F.; April 2d, it is below 101° F.; pulse, 80. The patient is unable to urinate voluntarily. During the first thirty-six hours after operation catheterization is regularly carried out two to three times in twenty-four hours, with the prostatic catheter sound. On the second day after operation there appeared a slight, progressive œdema in the suprapubic region, which slowly spread over the penis and scrotum down to the gluteal region.

April 3d: A Nélaton catheter on metal guide is successfully introduced and left in place; 157 ounces (4.710 c.c.) of urine are passed through the same in twenty-four hours. There is pain on pressure in the suprapubic region, and a slight resistance is palpable.

On April 4th drainage is less satisfactory; there is much vesical pain, which, however, yields under the administration of opiates. The soft-rubber catheter is exchanged for Mercier's and left in the bladder. The pulse at one time suddenly rises to 120, but soon drops again. Temperature not over 102° F.

April 5th: Pulse irregular; temperature lower, but soon increasing. Infiltration above symphysis. Suprapubic incision into cavum Retzii under eucaine was decided upon and set down for 2 P.M., when pulse and temperature suddenly rose after a chill and the patient's mind began to wander. Further interference was suspended. The patient continued to sink, and died on April 7th, at 1:30 A.M.

Post-mortem examination demonstrated a suppurative inflammation of the cavum Retzii and a far-reaching pericystitis, but no urinary infiltration. The bladder was found to contain a stone of about an almond's size. The galvano-caustic incisions are plainly visible. The posterior cut runs in the groove between the right lateral and median lobe (which latter is of tremendous size), and the left lateral incision transversely through the median lobe. The specimen is of great interest.

The unfortunate result in this case was evidently due to my still having carried out the anterior incision. Death clearly resulted from a suppuration in the cavum Retzii, due to infection by contiguity—not by perforation of the anterior bladder wall, since a careful examination at the autopsy failed to reveal any trace of perforation. It will be remembered that in my Case IX. I also observed pain on pressure above the symphysis. On traversing the cavum Retzii, when performing suprapubic cystotomy, on the eighth day after the operation, a very slight œdema only was found to be present. Recollecting this experience, I hoped at first that the complication might prove no more serious in this instance. Increasing evidence of local inflammation, however, soon convinced me that an incision was imperative; the sudden change in the patient's general condition prevented me from carrying out my intention. It had been my privilege, just before doing this operation, to listen at the Academy of Medicine to a most instructive demonstration of the anatomy of the prostate gland, by one of our New York colleagues. I believe to have understood the doctor at the time to say that, in a number of cases of marked prostatic enlargement, the posterior urethra was depressed by a mass of glandular tissue lying in front of the prostatic urethra. The large size of the gland palpated per rectum as well as seen through the cystoscope, made me think that just such a condition was present in this case. I therefore depressed the handle in order to divide the anterior prostatic tissue as thoroughly as possible. Of course, I now very much regret having done so. It was in consequence of this sad experience that I decided discontinuing the anterior incision. Only in those exceptional cases in which the cystoscope plainly will show the cause of an incomplete result after a first Bottini operation to be a mass of prostatic tissue situated above the internal sphincter (Freudenberg reports such a case) shall I, in future, lend my hand to make an anterior incision. That the beak of the incisor slipped off the median lobe at the beginning of the operation, and the galvano-caustic division then deepened the groove between the median and the right lateral lobe, happened by chance. It is questionable whether it would have proven beneficial to the patient. I personally am inclined to think so. It appeared to me from the specimen that the posterior urethra had been well lowered to the bas fond. On the other hand, a large median lobe frequently proves to be the main obstacle to proper drainage. I therefore think that, on the whole, it should be the aim to prevent the instrument from slipping off the median lobe and to try thoroughly to divide the tumor-like projection into the bladder, exactly in the median line. For such cases we will, of course, need the incisor which permits of making the cut 8 cm. long.

The indistinct yellowish spot I had seen through the cystoscope on the right side of the fundus, and which I could not explain at the time, was the stone. Had I introduced the stone searcher immediately afterward, the diagnosis could probably have been easily cleared up. As matters were, the patient was eager to get through with the one examination, and so it was omitted. In future, of course, I shall not again be satisfied with an indistinct abnormal spot in the bladder, but shall ascertain its meaning before doing Bottini's operation.

Case XVIII.—X——, a very active man all his life, has had increasing urinary trouble for the last four to five years. In May, 1897, the catheter was used for the first time; later it had to be resorted to occasionally. Soon the urine became turbid. In the fall of 1897 double epididymitis set in, which kept the patient in bed for three weeks. After this attack had been overcome urination was more free. In April, 1898, Bottini's operation preceded by cystoscopy was carried out by a competent surgeon. Cystoscopy, which was done rather hurriedly, had shown the bladder in a state of chronic catarrh, and demonstrated the pathognomonic groove at the internal urethral fold. Three incisions were made under eucaine, one directly posteriorly, the others at right angles. Very little reaction followed. The patient went back to his home five days later. He there had little chance to take proper care of himself. During the third week, after having jumped from a car, a vesical hemorrhage set in which necessitated catheterization and rest in bed. Six days later it recurred. The bladder then became more irritable and remained so for a long time. No special improvement could be observed as a result of the operation. One year later, in the early part of April, 1899, the patient consulted me. His condition then was as follows: urination every few hours day and night, sometimes accompanied with much pain; the catheter introduced after the act always found residual urine, varying in amount from two to over eight ounces. No blood; no renal elements. Cystoscopy, on April 8th, with the irrigating cystoscope, reveals the presence of four rather small concretions, lodged in a shallow groove to the left of the fundus. They are easily thrown aside by the water which is forcibly injected into the bladder through one of the channels of the cystoscope. When the latter is withdrawn into the vesical neck, two or three of the concretions follow and suddenly are seen to rest near the prism of the instrument. The characteristic groove at the neck of bladder is still present. The prostate can be seen in silhouette and shows distinctly two lateral rather shallow incisions running in a horizontal direction. In view of the presence of the stones, the second Bottini operation had, as a matter of course, to be deferred. Upon special request of the patient, the necessary intravesical manipulations were done under general anæsthesia. Thus, on April 11th, an attempt at washing out the stones with Otis' evacuator was made. To my delight two stones at once were drawn into the large opening at the vesical end of the catheter. They were freed by withdrawing the instrument. The latter was then re-introduced, but in spite of repeated efforts at extracting the other calculi by suction of the rubber bulb, this could not be completely accomplished, a portion remaining behind. Further operative interference was then desisted from, it being hoped that the patient might pass the last stone spontaneously. This, however, did not happen. On the contrary, absolute retention set in which necessitated regular catheterization. On the fifth day after the operation the patient again commenced to void a small amount of urine per vias naturales. On April 18th, cystoscopy was repeated. The remnants of the third and a fourth calculus, which had been broken in two when trying to remove the stones by suction, were plainly visible. It was determined to make another effort at evacuating the stones by flushing the bladder under general anæsthesia, and then immediately adding Bottini's operation. On April 20th this was successfully carried out, just as planned. The stones appeared promptly, and the galvano-caustic division of the gland could be at once added. On introducing and turning the incisor in order to hook the prostate, I was struck by the extreme softness of the organ. The finger when introduced into the rectum in order to palpate the beak of the incisor, could easily detect it about two inches above the sphincter ani muscles. After the necessary hugging of the gland, the tip of the beak was palpable immediately above these muscles. It was evident that the gland was of extreme softness. This recalled to my mind the case (XVI.) of exactly the same character in which I had operated a few months before, and in which I had the misfortune of doing an unintentional internal urethrotomy with the galvano-caustic knife. I therefore resolved to profit by my former experience, and to avoid, by all means, a repetition of the accident. As, however, my patient was ready to go to Europe, in fact had already engaged his berth, it was particularly desirable that the work be done radically in one sitting. In this emergency I made the median cut 2.75 cm.; the two lateral ones, at right angles, 2.5 cm. long each. The patient stood the operation exceedingly well. With the exception of some very severe pains setting in about two hours after the operation, which, however, could be controlled by a hypodermic of morphine, there was no reaction whatever. Absolute retention followed on the eve of the operation. I succeeded in introducing a soft-rubber catheter on a metal guide. Twenty-two ounces of a sanguinolent urine were evacuated. The bladder was washed out and the catheter left in place. On the following day some slight fever set in, which, on the second day after operation, at noon, reached 104° F. with a pulse of 116. Examination made of the perineum showed distinct symptoms of an abscess, which was immediately incised under eucaine. In holding the borders of the wound apart with sharp retractors, it was seen that the posterior incision had entirely cut through the prostatic urethra and a part of the membranous. The end of the two lateral incisions could also be detected from the wound. For convenience' sake a permanent catheter, introduced through the external meatus, was left in place and the wound tamponed. The temperature dropped promptly and was normal on the following day, the third after the operation, never to rise again. From now on careful vesical irrigation was carried out with the additional internal use of urotropin, caffeine, and strychnine. The catheter which had been introduced at the time of the perineal incision was not changed until May 1st, that is, the eleventh day after the operation. On removing it the patient at once passed from eight to twelve ounces of urine spontaneously, of course through the perineal wound, but the same was slightly tinged with blood. On the evening of the same day a rather alarming hemorrhage set in, which, however, was controlled by perineal compression; the catheter was purposely not introduced. Slight vesical hæmaturia followed and continued for four days. On May 12th, or the end of the third week after operation, the patient urinated for the first time per urethram. The perineal wound then rapidly contracted and soon definitely closed. The amount of urine voided every three to four hours was between six and ten ounces.

In the early part of June the patient left for Europe, where he spent a number of months. On his return in the fall he had very much improved in general condition, urinated spontaneously without discomfort, but invariably had to press out the last drops of urine with his hand on the perineal scar. He evidently had been much benefited by Bottini's operation, and there was every reason to hope that the trouble was permanently cured. To my sincere regret I learned that, three months after the patient's return from Europe, a residual urine, varying from a few drachms to a number of ounces, had again appeared, and that the vesical catarrh, which had been present for many years, was not materially improved in spite of continuous local and medical treatment. As far as I could ascertain, a sound of No. 8 American passes into the bladder without trouble, showing that no material contraction followed the unintended multiple galvano-caustic division of the posterior urethra. I am unable to account for the reappearance of the varying residual urine, but should not be surprised if it were found, on cystoscopic examination, that another small calculus is the chief cause of the trouble. It certainly is by no means excluded that further developments will yet show the second Bottini operation to have been a permanent cure. So far we can only claim "material improvement" in this particular case. The patient otherwise has considerably gained in weight, looks well, and is back in active work.

Case XIX.—S. H——, seventy-four years of age. The first urinary symptoms date back seven years: frequency of micturition; after-dribbling. Three years ago retention and overflow set in for the first time. The catheter was employed for a time, when he again was able to urinate spontaneously, about once every hour. For the last nine months ischuria paradoxa; urine discharged involuntarily. Eight weeks ago he consulted a doctor for the first time; 30 to 60 c.c. (1 to 2 oz.) were slowly passed; residual urine 960 c.c. (32 oz.). Vesical catarrh was present. The bladder was irrigated. Internal medication: salol, urotropin. No improvement was noted, but on the contrary, the patient got gradually worse. When he first called upon me, on May 6, 1899, he stated that he was regularly catheterized twice daily, and that generally 1,000 c.c. (33 oz.) were drawn off. In spite of this, the frequent desire to urinate persisted day and night, although he voided but a few drops each time, under great pain. Two days ago he had a chill, followed by fever. I requested the patient to urinate, but he was unable to do so. A Nélaton catheter then introduced without difficulty drew 285 c.c. The irrigating water soon returned clear. Length of urethra, 24 cm. The gland per rectum appears large. Its upper border can just be reached with the finger tip; it is of medium consistency and not expressible on massage.

Report of urinary analysis: Chronic cystitis without fermentation; nephritis, with most probably pyelonephritis.

May 5th: Cystoscopy; funnel of cystoscope needs much pressing down before beak slips into bladder. Hemorrhage from prostate. After change of water, a beautiful trabecular bladder can be viewed. The mouths of both ureters seem to be wide and gaping (hydro-ureter?). Characteristic groove at internal fold nicely marked. On turning the prism toward the fundus, a large projecting growth, evidently a part of the body of the prostate, becomes plainly visible. There is no stone. With the hope of reducing the blood supply of the prostate, resection of both vasa deferentia is done as a preliminary operation on May 22d. On May 24th the patient passes water spontaneously, first 150 c.c. (5 oz.), later 210 c.c. (7 oz.), residual urine 780 c.c. (26 oz.). On the following day he does not void more than 45 c.c. (1½ oz.).

On May 30th, 570 c.c. (19 oz.). are passed spontaneously, the greatest amount voided at one time being 180 c.c. (6 oz.). Residual urine 810 c.c. (27 oz.).

June 1st: 60 c.c. (2 oz.) is the largest amount passed without the catheter.

June 2d: Bottini's operation, under eucaine. On firmly hugging the prostate, the tip of the beak is palpable about one and one-half inches above the anus. Posterior incision 3.25 cm. long; the two lateral ones, both at an angle of 60°, 2 cm. After the operation the patient is unable to pass water. At 11 p.m. a soft-rubber catheter is introduced and 540 c.c. (18 oz.) of a slightly bloody urine are drawn off. The catheter is left in place. The next morning the urine is free from blood. The temperature that day rises to 101°; pulse normal. A slight elevation in the temperature toward evening was noted the following days; it never exceeded 101.3°, however. The patient complains of pain in the left testicle.

June 10th, eight days after the operation, the permanent catheter is removed. Catheterization becomes necessary twice that day.

On the 11th of June he commences to pass water spontaneously, the first amount being 180 c.c. (6 oz.). which is followed by a voluntary discharge about every hour. The catheter is dispensed with.

On June 12th, the greatest quantity of urine voided at one time is 240 c.c. (8 oz.), the total discharge in twenty-four hours being 1,980 c.c. (66 oz.).

June 13th: Total amount passed 2,190 c.c. (73 oz.).

June 14th: Quantity voided in twenty-four hours 1,050 c.c. (35 oz.). The catheter introduced at 5 p.m. finds a residual urine of 690 c.c. (23 oz.).

The next day the catheter has to be used twice, and is again dispensed with on the 17th of June, never to be employed again. Within the last days the patient complained frequently of much pain along the left spermatic cord and in the testicle. Temperature is rising. A palpable infiltration is running through the inguinal canal down to the spot of the ligation of the vas deferens. Funiculitis; epididymis not involved. The infiltration is incised on June 19th, and pus evacuated. After this the quantity of urine voided spontaneously rapidly increases and is, for instance, on June 26th, 240 c.c. (8 oz.). The greatest amount passed at one time on July 3, is 300 c.c. (10 oz.); on the 12th of July again 300 c.c. (10 oz.). This nicely shows the increasing capacity and decreasing irritability of the bladder. During the summer the patient returned under the care of his family physician, who regularly dressed the sinus on the left side of the scrotum, which proved rather obstinate, but permanently closed about six months after the operation.

November 7th: The patient states that he urinates every two to three hours during the day; nights twice. He has never used the catheter since it was laid aside soon after the operation. He has a good stream, but catarrh of the bladder is still present. Continued irrigation is strongly urged.

Final examination, April 16, 1900: Patient empties his bladder every three hours during the day; nights generally a quart, in two to three times; forcible stream; no pain; he has gained considerably in weight; bowels normal. The fistula resulting from the funiculitis closed three months ago. He has no desire to urinate, but on request passed 75 c.c. (2½ oz.); residual 225 c.c. The urine contains a large amount of pus; marked pyelitis; the catheter has not been used again since the operation. The length of urethra is 23½ cm. Patient feels as if he had regained perfect health.

In reviewing the temperature chart of this patient, it is evident that the temperature rose in proportion to the length of time the permanent catheter remained in place. I feel that it was worn an unnecessarily long time. Three days might have been sufficient. Had I removed it then and catheterized the patient at regular intervals, the funiculitis might perhaps have been avoided. As stated before, I am not in favor of putting in a permanent catheter immediately after the operation in every instance, but prefer to wait and see whether the patient is not able to urinate voluntarily. If this is impossible, I consider it better for the patient in the end if he is catheterized at regular intervals, provided the introduction of the instrument is not attended with any particular difficulty. The permanent catheter generally forces the patient to stay in bed.

Case XX.—W. W——, seventy-one years of age. His first trouble in micturition dates back thirty years, the first symptoms being that he had to press long and felt a burning sensation in his urethra. He never had an attack of gonorrhœa or specific disease. At that time sounds were passed, used for a year or two, and brought relief. The diagnosis made by his attending physician was prostatic hypertrophy. The following ten years he felt much improved, but never entirely well. Twenty years ago, during a severe attack of dyspepsia, the prostatic trouble increased. Absolute retention set in, which necessitated catheterization; since that time he never got entirely rid of the catheter. Very often he was absolutely unable to void a drop of urine for an entire day and night, and then again he was better for several weeks. Fourteen years ago the urine often contained blood, principally in winter time. The patient claims to have frequently suffered from chills and lumbar pain, more on the left than on the right side. Five years ago a turn for the worse took place. He had to catheterize himself oftener, sometimes every hour, and suffered very severe tenesmus and hæmaturia. Careful irrigation carried out for three weeks brought improvement. The patient noticed that whenever the urine was tinged with blood, urination was free, but as soon as it cleared trouble set in. He also frequently suffered from epididymitis, sometimes on the right, sometimes on the left side. Four years ago a doctor sounded him for stone. Result, several days of continuous severe hæmaturia; three weeks of intense pain. Since then he avoided all further examinations. Lately he urinated about every hour during the day and used a catheter at night before retiring; this allowed him to rest until midnight, when he would have to draw off the water again, and a third time before morning. When first seen by me, June 15, 1899, the patient, a strong, robust man, was able to urinate 40 c.c., showing a residual urine of 75 c.c. On irrigation the water soon returned clear. Of 200 c.c. injected into the bladder 100 c.c. could be passed. The prostate per rectum was soft and very large in all its lobes. I personally was able to reach its lower portion only; a friend of mine with an extremely long forefinger was also unable to reach its upper border.

Analysis of urine: Acid; albumin, 0.25 per 1,000; urea, 26.4 gm. in twenty-four hours; no sugar; few cells of blood; moderate amount of pus and mucus; some hyaline casts; some blood cells and groups, presumably from renal pelvis; small amount of uric acid. Conclusion, hyperæmia of renal parenchyma with slight vesical catarrh.

On January 19th, cystoscopy with irrigating cystoscope. The instrument has to be introduced to its full length before the cavity of the bladder is reached. The light having been turned on, it is at once seen that the prism is still in the region of the prostate. One sees the characteristic groove not in the median line as is usual, but somewhat to the right side of the patient. That side of the angle near the median line rises perpendicularly upward like a massive wall, and is seen to be covered with multiple polypous excrescences, after the cystoscope is pushed farther in. There certainly is a median lobe of very large size. It is extremely difficult to turn the instrument 180° in order to observe the fundus. It is possible only after additional 250 c.c. of water have been injected into the bladder. There is no stone. In pressing down the handle of the cystoscope, a procedure which is exceedingly painful to the patient, one clearly recognizes a large mass projecting into the bladder (body of the prostate). I did not, of course, hesitate to make it plain to the patient that in his case Bottini's operation might be followed by a great deal of trouble. However, the patient was so thoroughly tired of his condition that he was ready to undergo the procedure at all hazards.

Bottini's operation was done on June 21st. On hugging the prostate the handle of the incisor was forcibly pressed, evidently by the peculiar configuration of the gland, toward the right of the patient. It was, therefore, very difficult to keep the instrument exactly in the median line of the body. It was clear that the large median lobe had been turned back and forcibly resisted, being twisted upon itself. At that moment I felt the necessity of having on hand the instrument with which I could cut as long as I might wish to within the limits of 8 cm. For my friend, who, with his finger in the rectum of the patient trying to localize the distance of the tip of the incisor from the sphincter ani muscles, was just able to feel it, and his finger measures 12 cm. As matters were, I could make only three cuts, one in the median line directly posteriorly, one through the right lateral lobe at 45°, and one through the left at 90°, 4 cm. each. The result was just what we had expected. The injured median lobe rapidly increased in size by reactive swelling and represented an unyielding barrier to the entrance of all instruments, gum-elastic and solid, that we tried to introduce through the normal channel. Absolute retention set in, and all attempts to bring relief in the usual way were futile. Puncture of the bladder above the pubes became necessary and was carried out eight times (twice per day) within the next five days. Strict asepsis being observed, no trouble ensued. Prior to entering the bladder with the trocar, each time a different spot of the skin within the short distance between the symphysis and the lower end of the pre-vesical peritoneal fold was selected. As a preliminary the skin was here incised under local anæsthesia for about one-eighth of an inch, always in the transverse direction.

On June 26th, five days after the operation, I succeeded for the first time in introducing a Nélaton catheter on a metal guide. This was left in place and gave the patient a great deal of relief. Meanwhile the scrotum had become swollen to tremendous size. The pulse was between 90 and 106; the temperature had never risen above 101.6° F., nor had there been a chill at any time. These facts, in conjunction with absence of infiltration in the perineum, showed that urinary infiltration had not set in. I could, however, not explain the œdema of the scrotum in any other way than by assuming that some infecting material had leaked out; perhaps the phenomenon was to be considered a microbic infection by contiguity.

On June 30th, nine days after the operation, multiple incisions through the scrotum, under eucaine, with proper drainage, became necessary. All the tissues down to the tunica vaginalis propria were densely infiltrated, without, however, showing the slightest trace of pus.

On July 3d, the permanent catheter was removed for trial. The patient was unable, however, to pass a drop of water. In order to facilitate treatment a catheter was again introduced and permanent drainage continued until July 12th, that is, the twenty-first day after the operation. Some six hours after the removal of the instrument the patient passed about half an ounce of thin bloody fluid, and once more half an ounce of the same fluid two hours later. Then absolute retention again set in, and regular catheterization every six to eight hours became necessary. It was, however, much easier than before. By July 18th catheterism had become so painful and the spasms of the bladder were so severe, that relief in some way had to be obtained. In my opinion only a second Bottini's operation could be of use. It was done with the incisor allowing of an incision 8 cm. in length, on July 20th, or twenty-nine days after the first operation. The incisor slid into the bladder with great ease; its handle was not forcibly pressed toward the patient's right side, as had been noticed during the first operation. On pulling from without, the instrument suddenly slipped into a deep groove for at least an inch (same as in case XIV.), an occurrence which caused me to abandon my original idea of making the incision 6 to 7 cm. long. Instead, I made a posterior cut of but 4 cm. in length in the median line and one of the same length through each lateral lobe. A Mercier English webbed catheter, No. 17 F., was introduced immediately after the operation was completed. It entered with remarkable ease and was left *in situ* for five days. Reaction was comparatively slight. There was some rise of pulse and temperature, the former reaching 118 at one time; the latter stayed below 101.4° F.

On July 21st, the nurse's report states: "The patient passed a very comfortable night; drainage per catheter was good, 38 ounces in twenty-four hours."

On July 25th, the fifth day after the operation, the permanent catheter was removed. The patient was still unable to urinate voluntarily. Regular catheterization with bladder irrigation had, therefore, to be resumed, and was carefully carried out every four to six or eight hours.

On July 27th the patient, for the first time, remained out of bed for some time, and thenceforth got up for a longer period every day.

On August 6th, the seventeenth day after the second operation, and the forty-sixth day after the first, the patient for the first time, and under considerable pain, voluntarily passed 2 ounces of slightly bloody urine. Four hours later he passed 3 ounces, and one hour later again 3 ounces. On August 8th, he passed 18 ounces within twenty-four hours; residual urine as drawn per catheter, between 9 and 15 ounces. On August 9th he passed 25 ounces in the course of twenty-four hours, and on August 14th 39 ounces. Improvement then steadily continued.

In the early part of September the patient left for the country, where he took baths and massage. When I saw him again, on October 11th, he reported that he had not had to use the catheter at all for six weeks. He urinated about every hour and a half during the day; four to six times during the night, in a good stream and without pain. Now and then there is irritation at the neck of the bladder so that the patient has difficulty in retaining the urine when the call comes. Otherwise he feels perfectly well. Since that time the patient's condition has still more improved, as I learned a few days ago. He so far did not present himself at my office.

CASE XXI.—The history of this case is, it seems to me, not only of unusual interest, but also of great importance. On November 25, 1898, I removed three large, heavy uric-acid stones from the bladder of a patient forty-nine years of age, who, on rectal palpation as well as on cystoscopy, had shown quite a degree of prostatic hypertrophy. The urine at the time of the operation, which was done seven years after the onset of his troubles, was extremely fetid. In spite of ample gauze drainage of the wound and proper siphoning of the bladder with the T-tube, the perivesical connective tissue became necrotic after the operation. It was two to three weeks before all the sloughs had been pushed off. It was eight weeks before the patient could be discharged from the hospital. At that time he still suffered from a severe neuralgia in both sacral plexuses, which was in time overcome by warm baths, rest, and massage. There remained, however, a very rebellious suprapubic fistula through which at least half of his urine was discharged. During the summer months it closed for a short time, but soon opened again after the formation of a perivesical abscess. Cauterization carried out in various ways had no effect. On injecting 200 c.c. of a sterilized boric-acid solution 150 to 175 c.c. were passed simultaneously through the urethra and the suprapubic fistula; the catheter then withdrew 25 to 50 c.c. of residual urine. In the early part of October about half of the urine was discharged through the fistula. Cystoscopy carried out at that time showed the typical groove at the neck of the internal urethral fold. According to the view already expressed in my last article on the subject of Bottini's operation, namely, that it was to be hoped that such an obstinate suprapubic fistula might eventually be brought to a permanent close by means of Bottini's operation, I proposed the latter to the patient.

It was carried out at the German Hospital on October 11th, under eucaine. Three cuts were made, one posteriorly, 4 cm. long; one through the right lateral lobe at 45°, 3.75 cm. long, and a third through the left lateral lobe at an angle of 90°, 3.5 cm. long. There was no reaction. The patient was kept on his back and soon commenced to pass the greatest amount of his urine through the urethra. The suprapubic fistula, which before had been filled with somewhat protruding granulations, soon became shallow and then funnel-shaped. Three weeks later the patient was discharged with his trouble much improved, though not entirely cured. On November 21st, he urinated 70 c.c.; residual urine, 25 c.c. Of 300 c.c. injected, every drop is passed through the urethra in a very forcible stream. There is still some slight leakage through the suprapubic fistula. It is impossible to introduce a probe into the bladder from without. Cauterization of the fistula with the actual cautery could thus not be done. And I was not eager to do it, for it seemed to me that in this case the aim should be not to destroy more tissue, but to cause that which was present to heal by chemical stimulation. I succeeded on that day in injecting 10 c.c. of pure balsam of Peru into the bladder, which had previously been filled with sterile boric-acid water. On passing the latter through the urethra, the balsam of Peru escaped with it. This procedure was repeated three times at intervals. Still, there was some slight leakage, sufficient to saturate gradually the piece of gauze that was worn by the patient in front of the sinus. I therefore decided to increase the strength of the chemical application, and on December 9th I injected 200 c.c. of sterilized water into the bladder, and then with a small glass syringe forced into the bladder through the sinus 15 minims of pure carbolic acid (thus making a one-half-per-cent. carbolic solution in the bladder), a procedure which was immediately followed by an injection of pure alcohol. Five days later the patient reported that there had been absolutely no leakage through the sinus since this cauterization, and from that time on not a drop has ever passed by the suprapubic route.

Final examination, March 29, 1900: The patient urinates five to six times during the day; nights not at all; good stream; no pain; the suprapubic fistula has remained closed; he has gained considerably in weight; bowels normal. While at my office he passes 130 c.c., residual urine 20 c.c. The urine is entirely clear. Of 250 c.c. nitrate-of-silver solution, 1 : 5,000, injected, every drop is passed. Matrimonial intercourse regular and enjoyable. The patient was presented before the Section on Surgery of the New York Academy of Medicine, April 9, 1900.

In view of the success of the operation in this case I have become somewhat doubtful as to the advisability of trying to perform litholapaxy in the majority of prostatics as a preliminary measure to Bottini's operation. We all know how much the prostate often resents prolonged instrumental interference; how, after litholapaxy, an incomplete retention may suddenly become complete. Hence, the possibility of an already present pyelitis assuming a much more serious aspect after the said procedure must be apparent. With my present experience, therefore, I should, in cases of a doubtful prognosis, prefer doing suprapubic lithotomy as the first step, adding, if necessary, Bottini's operation at a later period.

The question as to whether it would not be advisable to do both operations at the same sitting, thus being enabled to put the instrument in place under the direct guidance of the eye, cannot yet be decided. It is true, it is generally three weeks before the eschars are pushed off, at which time the suprapubic wound ought to be nearly closed and the flow of urine through its normal channel could be resumed. If, therefore, both these phenomena occurred at the same time, all would be well. On the other hand, with retarded wound healing, the grooves cut through the prostate might become more or less completely obliterated on account of there being no urine passed through them to prevent it.

With regard to the prognosis of Bottini's operation in this class of cases, it is reasonable to assume that most of the patients will better stand it than those not afflicted with urinary leakage above the pubes, on account of the presence of the suprapubic fistula. If by reactive swelling of the gland the normal passageway should first become temporarily blocked, the fistula will give easy exit to the urine.

I believe that this case is the first of its kind in which so obstinate a suprapubic fistula was brought to a close by Bottini's operation. The case proves that to this class of sufferers also Bottini's operation may prove of immeasurable benefit. I have no doubt that it is destined in most of these cases to take the place of bilateral castration, the only hope of a cure that could so far be held out to these poor patients.

Case XXII.—B——, seventy-two years of age. He has suffered for the last three to four years from increasing urinary symptoms; lately absolute retention; regular catheterization. Two months ago he had a cellulitis of the right hand, which was treated by the family physician with repeated multiple incisions. The patient was sick for over six weeks. He was seen by me in consultation October 11, 1899, on account of the absolute retention. The patient was greatly emaciated. The prostate was large and soft; its upper border could be reached with the tip of the finger. Prostatorrhœa; vesical catarrh. Temperature varied between 100° to 101° F.; pulse not above 100.

October 14th: Cystoscopy. Trabecular bladder; pathognomonic groove at internal fold not very marked, but internal fold irregular, thickened, not transparent; cystitis.

Urinary analysis: Chronic nephritis; no apparent renal lesion of renal pelvis; chronic cystitis.

Bottini's operation was performed on October 18th at 8 A.M., the patient having been carefully prepared by the internal administration of quinine and urotropin. The prostate was found to be extremely soft; after compression the tip of the beak was palpable about one inch above the anus. Posterior incision 1.5 cm. in length; the one through right lateral lobe at an angle of 45°, that through the left lateral lobe at 90°, 1 cm. each. Two hours after the operation the patient voided 120 c.c. (4 oz.) of urine mixed with the fluid which had been injected into his bladder, and continued urinating in somewhat smaller quantities every hour or hour and a half, passing 2,010 c.c. (67 oz.) of slightly bloody urine within the first twenty-four hours. At 5 P.M. of the same day, nine hours after the operation, the patient had a slight chill, followed by rapid rise of temperature and pulse. At 7:30, temperature, 105° F.; pulse, 104. At 10:30 P.M. temperature, 104.8° F.; pulse, 120. Pulse and temperature then gradually declined and reached normal on the morning of the third day after the operation. Seven hours after a second chill, which lasted thirty minutes and occurred on the third day after the operation, phlebitis involving the saphenous vein of the left thigh set in. The patient had had marked varicose veins for many years, but, as he stated, never an inflammation. His general condition was good. The spasms at the neck of the bladder had discontinued; there was no more pain. He voided his urine spontaneously every three to four hours in quantities of 150 to 270 c.c. (5 to 9 oz.). Although the phlebitis had to be looked upon as an annoying complication, I considered the patient out of immediate danger and rejoiced with him in the improvement of his vesical trouble. On October 22d, the fourth day after the operation, he passed about 330 c.c. (11 oz.) at one time in a good stream. The following days the pulse was very satisfactory, never above 100; but the temperature fluctuated between 101° and 104° F. The stomach was rather irritable, but the bladder acted perfectly normally. On the fifth day after the operation the patient passed 1,650 c.c. (55 oz). within twenty-four hours, in six times. However, his general condition did not keep pace with the improvement in the functioning of the bladder. The pulse began to rise again, and on October 28th (ten days after operation) reached 128; temperature, 104° F.; respiration, 40. Urine voided at one time, 480 c.c. (16 oz.). Physical examination demonstrated the presence of a lobular pneumonia, to which the patient succumbed on October 29th, eleven days after Bottini's operation.

To my regret, a post-mortem examination was refused, and I was, therefore, unable to determine whether the lung affection was due to hypostasis or to an embolism. For the reason that the saphenous vein has no direct communication with the internal iliac vein, the one which might become thrombosed after Bottini's operation, I can explain the peculiar occurrence of a phlebitis on the left thigh only by assuming that streptococci were still present in the circulation of the patient from the time of his cellulitis. The slow and weak action of the heart, in conjunction with the equally slow and weak current of blood in the varicose veins, then produced thrombi in the latter, in which the streptococci of course found a most favorable soil. It is certain that the patient did not die in consequence of Bottini's operation, as such. On the contrary, his bladder functions were restored in a most admirable way and in so marvellously short a period as I have not seen occur before or since. What evidently caused his death was the phlebitis with probably following embolism.

Case XXIII.—M. K——, seventy-two and one-half years of age, has been suffering from symptoms of prostatic enlargement for the last six to seven years. Retention has repeatedly had to be relieved by catheterization. Often the region over the kidneys was painful. The patient came under my care during the summer of 1899, when he was suffering from a mild sepsis, suppurating prostatitis, pyelo-nephritis, and cystitis. Micturition was very painful. The prostate was found to be very soft; its upper border could be reached per rectum. Frequent slight chills and rise of temperature were improved under regular catheterization and vesical irrigation. Residual urine was never below 540 to 600 c.c. (18 to 20 oz.). The amount of urine passed voluntarily within twenty-four hours, at very frequent intervals—every half-hour to hour—was between 1,200 and 3,000 c.c. (40 to 100 oz.), the quantity daily withdrawn per catheter being from 1,000 to 1,800 c.c. (33 to 60 oz.). Urinary analysis: Chronic pyelo-nephritis and cystitis. In view of this condition cystoscopy was omitted.

After a few months' treatment the patient strongly urged me to perform Bottini's operation on him. Naturally, I did not feel much inclined to do it. He insisted, however, being anxious to get rid of the catheter, so that finally I acceded to his wish, and, after careful preparation of the patient, performed Bottini's operation on October 9th. One median incision, 3 cm. long, was made very slowly, as usual. The lateral cuts were omitted. No improvement resulted. Micturition was painful and frequent. Ten days later, October 19th, Bottini's operation was repeated. Median incision 4 cm.; through right lateral lobe at an angle of 45°, 3.5 cm.; through left lateral lobe at about 75°, same length. Four hours after the operation, the patient commenced urinating, and from then on passed between 3,000 and 3,500 c.c. (100 to 116 oz.) daily. There was only a very slight reaction. Temperature on the second day was 101.8° F.; pulse never above 100. On the third day both declined to normal. On October 28th, the patient complained of a great deal of fulness in the lower abdominal region, although he had passed 3,810 c.c. (127 oz.) of urine within twenty-four hours. The catheter thereupon introduced withdrew 840 c.c. (28 oz.) of residual urine. Thereafter he was regularly catheterized once in twenty-four hours, and the amount of residual urine began to decrease after the eschars had been pushed off in large numbers during the third week.

On the 4th of December the patient left for his home in the West. He felt better in every respect and had gained in weight. Residual urine had dropped to 210 to 240 c.c. (7 to 8 oz.). As its presence did not cause the patient any inconvenience, further interference was advised against. The urine still contains a good deal of pus.

In a letter to me, dated April 23, 1900, the patient states: He urinates every four to five hours in the daytime, once on retiring at 9 P.M., and twice thereafter; he has not a bit of pain; the stream is good and strong; catheter not used since departure from New York; does not think that there is any residual urine (to my regret, it was not tested); bowels more regular; general condition very good; has gained about eighteen pounds.

This case nicely shows that Bottini's operation may be done with impunity even in patients who suffer from pyelonephritis. This patient certainly belongs at present to the category of "much improved" cases. Had the amount of residual urine been tested at the time of the last report, it might be shown that the case had to be included in the class of "cured" (so far).

CASE XXIV.—L. Z——, sixty-two years of age. Increased frequency of micturition first noticed after a long bicycle ride, about two years ago. It was accompanied with pain and slight hæmaturia. Since that time he could not retain his urine as well as before, and the calls, too, generally came oftener than previously. The most annoying feature, however, was that at the advent of the call a painful erection regularly set in, and a few drops only of urine were passed. After an interval of five to ten minutes, during which the pain did not cease, and under considerable straining, a weak stream of urine appeared. About a year ago he urinated every two to three hours during the day, once or twice during the night. Being obliged to make extensive tours through the States, he often had attacks of very frequent micturition, every ten minutes, an occurrence which, in the light of future developments, will probably have to be looked upon as overflow. Around Christmas, 1899, undisputed retention set in for the first time. By the advice of a friend who was similarly afflicted, he used a rather stiff rubber bougie, of about No. 12 French. With this he evidently injured his urethra in the region of the cut-off muscle, for when his doctor tried to relieve him by catheterization, quite a severe hemorrhage occurred before the catheter had reached the prostatic urethra. When I saw the patient with the doctor, later in the evening of December 28th, the upper border of his bladder was palpable about two fingers' width above the umbilicus. Knowing from experience the difficulties so frequently encountered when catheterizing these patients with absolute retention and a profusely bleeding prostate, I placed the patient's pelvis upon a hard pillow and at once made use of Trendelenburg's prostatic catheter sound (No. 14 French), repeatedly referred to in this paper. I succeeded in entering the bladder and relieving the patient at the first attempt. Prolonged retention followed, which necessitated catheterization and irrigation of the bladder every eight to twelve hours. Digital examination showed the prostate to be of the size of an apple, neither hard nor particularly soft; its upper border could just be reached with the finger. Length of urethra, 22 cm. About two weeks after this he began spontaneously to void urine in small quantities, not exceeding 150 c.c. (5 oz.) at a time, and always under a great deal of pain. Residual urine was never less than 300 c.c. (10 oz.). Cystoscopy was omitted on account of the patient's great sensitiveness.

Urinary analysis, January, 1900: Glycosuria (0.3 per cent.); no lesion of renal parenchyma or pelvis; slight chronic cystitis. An analysis made two weeks later proved the sugar to have disappeared.

After carefully preparing the patient with urotropin, salol, and quinine, Bottini's operation was performed under eucaine, on January 13, 1900, the bladder being filled with 150 c.c. (5 oz.) of a two-per-cent. sterilized boric-acid solution. There was no concretion palpable with the beak of the incisor. The prostate having been hooked, the tip of the instrument could be felt with the finger in the rectum, about 8 cm. above the anus (median lobe!). The lower border of the prostate was estimated at 4 cm. from the anal ring. The median incision was therefore made 4 cm. in length; the two lateral incisions at an angle of 45°, 3.5 cm. The patient stood the operation very nicely, and stated that he had not felt the burning in the least, but had experienced pain throughout the entire length of the urethra, due probably, as I believe, to the firm hugging of the prostate. Two, five, and nine hours, respectively, after the operation, he passed a drachm of urine; twelve hours later a full ounce; 750 c.c. (25 oz.) of slightly bloody urine were then withdrawn per catheter and the latter left in place. There was no febrile reaction whatever. The permanent catheter seemed to become obstructed at times, but a few ounces of the usual irrigating fluid, thrown into it with a hand syringe, restored proper drainage.

January 16th, three days later, the permanent catheter was removed; but 30 to 60 c.c. (1 to 2 oz.) is the largest quantity discharged by the patient. He is, therefore, regularly catheterized and his bladder irrigated every eight hours.

January 18th: same status; the spasms are more frequent; otherwise his general condition is very satisfactory.

January 20th: A second Bottini operation is contemplated. On the morning of the following day, however, the patient voided 90 c.c. (3 oz.) at various intervals, so that the catheter withdrew only 90 c.c. of residual urine.

January 23d: Urination painless; increasing quantities passed at more frequent intervals.

On the 25th of January he passed as much as 150 c.c. at one time. The catheter was then dispensed with.

March 9th: The patient feels splendid; urinates about 2,100 to 2,400 c.c. (70 to 80 oz.) in twenty-four hours, eight times during the day; nights, three times. Occasionally passes 400 c.c. (13 oz.) in one act. There is no pain whatsoever; urine is very slightly turbid. Eschars have been discharged up to two days ago. He continues to take salol and urotropin. Bladder irrigations were advised.

April 10, 1900, ten weeks after operation: Last eschar passed two weeks ago; he urinates without pain every two to three hours during the day; nights once, that is to say, one time within ten hours; bladder holds easily 400 to 420 c.c. The stream is better than ever before in his life; urine cleared up entirely. Painful erection previous to the act of micturition has ceased since the day of the operation. He feels excellent; weighs more than he did any time within the last ten years: bowels normal; matrimonial intercourse regular and much enjoyed.

THE MODERN TREATMENT OF DIABETES MELLITUS.

By FREDERIC KRAUS, Jr., M.D.,
CARLSBAD.

Considering how small is our knowledge regarding the etiology of this disease even at the present day, we are obliged to renounce the causal therapy and concentrate our attention on a purely symptomatical one. The principal symptoms of diabetes are glycosuria and the malnutrition caused by constant loss of non-assimilated nutritive material.

Since the disease became known, nearly all physicians tried to reduce the glycosuria by restricting the carbohydrates in the food. During a very short period a very small number of physicians were led by the entirely false conclusion that a greater amount of carbohydrates must be introduced into the diabetic organism to make up for the loss caused by glycosuria; one of them was the celebrated physiologist Schiff, who, himself a diabetic, thereby hastened his own death. The medical therapy by drugs has shown itself in nearly all cases, by careful scientific investigation, to be a failure as far as the patient is considered, the drug-manufacturer only profiting. If there is any good effect, it is certainly due to the diet observed during the use of the drug—without diet there is no diminution of the glycosuria. The opiates are exceptions, but various reasons make us reserve them for the very severe cases only. The different preparations of hydrargyrum may be used in the very rare cases of syphilitic (diabetic) glycosuria, also balneotherapy and hydrotherapy, but both of these have also to be combined with dietetic treatment; I shall say a few words about them later. Therefore the only remaining treatment is the dietetic one (*Ernährungstherapie*). The object of this is, in the first place, not simply to reduce the glycosuria, but to keep the patient in the best form of nutrition, which naturally results from reducing the glycosuria as much as possible and replacing the excluded carbohydrates by other nutritive material of the same calory value.

The best way of finding out the proper diet in individual cases is the following (Kuelz, Naunyn, v. Noorden, etc.): The patient is put for one day on a "standard" diet, as v. Noorden calls it, which contains, besides the indifferent albuminous and fat-producing material, a certain amount of carbohydrates, for instance, 100 gm. wheat bread per day, which contains about 60 gm. of carbohydrates. Then the patient is told to collect twenty-four hours' amount of urine (he must begin with the urine passed immediately after the first breakfast and finish with the urine passed the next morning before breakfast). This method is used in all cases in the clinic for diabetics of Professor v. Noorden at Frankfort on Main. Then the amount of sugar passed during twenty-four hours is ascertained by polarization and titration, or by polarization before and after fermentation, to find out also the amount of substances which turn the plane of polarization to the left.

There are now three possibilities: (1) that there is no sugar at all; (2) that there is less; (3) that there is more than 60 gm. of sugar excreted with the urine. The first we find in all mild cases of diabetes and in all cases of non-diabetic glycosuria. In all of these cases after a period of four to five days the daily portion of carbohydrates is increased by a certain amount, between 30 to 50 gm. of bread or an equivalent of carbohydrates in another form. The urine of the last day of such a period is collected in the formerly described way, and this is continued until a trace of sugar is found in the urine; then we know what amount of carbohydrates the organism is able to assimilate, *i.e.*, "its tolerance for carbohydrates." Then the patient is kept for one or two days on a very strict diet, in order to make the traces of glycosuria disappear entirely, and thereafter the amount of carbohydrates in his diet is increased gradually day by day up to the highest amount which he is found able to assimilate.

In the other cases in which glycosuria is found the amount of carbohydrates in the patient's diet is reduced until a diet is obtained as free from carbohydrates as possible. This reduction must be effected gradually, as a sudden deprivation is very often followed by disagreeable symptoms of collapse. The patient is then kept on that strict diet for three or four days; on the last day the urine is collected in the formerly described manner, and if traces of glycosuria are still found, such periods of strictest diet may be repeated, or we may even, if we fail to free his urine from glycosuria, restrict the amount of albuminous food (Naunyn, v. Noorden, Pavy, etc.), substituting fat for it. The fat is then given with certain vegetables which contain a very small percentage of carbohydrates, which amount can be reduced still further by a certain method of cooking. But during all this time the greatest care is necessary; we must interrupt such a severe diet if we find the patient is rapidly losing in weight, and we must also carefully examine the urine to find whether there is azoturia, whether the amount of acetone is high, and whether diacetic and oxybutyric acids are in the urine. Therefore it is also recommendable to give large quantities of bicarbonate of sodium daily, to avoid hyperacidity of the blood (Naunyn, Stadelmann, Magnus-Levy).

After the glycosuria has disappeared, we begin again to add small doses of carbohydrates to the diet till the highest limit is reached, proceeding as in the mild cases. It is well known that periods of abstinence increase the assimilating force and that the continued use of carbohydrates diminishes the same, therefore the patient should also be told to include from time to time, at regular intervals, three to four days of strict diet, for instance the last three to four days of each month or every second month. These intervals are to be chosen according to the severity of the case. After these four days the carbohydrates are to be increased again up to the allowed amount. The urine is to be examined immediately before the periods of strict diet, in order to ascertain if there is any change in the amount of glycosuria. In other cases, in which it is impossible to suppress the glycosuria, even by strictest diet, we must also allow the patient a certain, though small addition of carbohydrates to his daily diet, for the following reasons: (1) If not allowed, the patient would nevertheless take it by himself. (2) We know that to live for any length of time on a diet consisting exclusively of albuminous material and fat is impossible for the human organism; but in these cases we will include the periods of strictest diet at shorter intervals, and of five to six days, if the general health of the patient permits it. There are further cases of diabetes in which any sort of antidiabetic diet is nothing but a superfluous cruelty to patients whose days are already numbered.

It is also of great value to know in each case the fluctuation of glycosuria within twenty-four hours, an exact knowledge of which will in many cases allow the possibility of a very liberal diet.[1] At any rate it is always advisable to add the given carbohydrates to the more copious meals, dinner, lunch, and supper, and to avoid them more or less at breakfast. But it is not only a question as to how much carbohydrates may be given, but also in what form they are best given. The best way is to give those carbohydrates which the patient is accustomed to have; first of all to allow him a certain quantity of the bread he is in the habit of eating. It is only necessary that the prescribing physician should know approximately the percentage of carbohydrates in those articles of food which he is willing to put on the patient's diet list. During the first few weeks the patient will have to use scales, but later on he will learn to guess the weight of his food articles by their size, etc. Surrogate food is in the most cases easily avoidable. No surrogate will ever reach in taste the real thing; therefore the patient very soon gets tired of it, and, to choose a common example, he will soon prefer a small piece of plain bread to a large piece of a less palatable surrogate. Besides, there are advertised, especially recently, a great many surrogates which are not at all reliable. I have personally had occasion to examine a great number of them, and, using the method of Allihn, which always gives very exact results, I found that some of them contained just as much carbohydrates as the common flour and bread. But there are also some very useful surrogates and preparations.[2]

As said before, in order to make out a good diabetic diet list one must approximately know the percentage of carbohydrates in the various articles of food, and must also know how to substitute the excluded carbohydrates so as to satisfy the want of calories, just as well as the exertions of appetite and taste, and this requires not only scientific chemistry, but also some culinary knowledge and experience, which are easily obtained.

In regard to alcoholics, opinions vary, but used moderately and with careful selection they certainly deserve a place in the diabetic diet list; the quantity, however, must be so chosen as to exclude any toxic effect.

It is easily recognizable that all this is connected with a great many difficulties in an all-around, general practice. A treatment like this not only consumes a great deal of the doctor's and of the patient's time, but it may sometimes even be impossible for a person who is very active either in business or in social life to follow all these directions. In order to avoid all those difficulties it is best to send the patient, as soon as the diagnosis is made and other circumstances allow it, into clinical treatment, either to a hospital or, if the patient has means enough, to one of those private clinics which are entirely devoted to diabetic patients. Then he will not only be under careful examination and control, but—and that is one of the greatest advantages of these clinics—he will learn there how to live after having returned to his home, and then it will be very easy for the family physician to keep the case under control.

The balneo-therapeutic treatment has also maintained its place in the treatment of diabetes, and the many good results attained thereby rather speak in its favor, although strictly clinical experiments have shown no results at all. The effect of balneo-therapy in diabetes is not founded on the special water only, but on the combination of many other circumstances. First of all the patient, leaving his home, leaves behind him all trouble and worriments, gets a rest from his daily life (and we all know what an influence rest and change of surroundings have on a diabetic patient); he is better able and more willing to obey strictly all that is asked of him by his medical attendant. He will find at nearly all the hotels and restaurants, at least in all the famous European spas, a list of dishes which are free from carbohydrates, generally marked out as dishes for diabetics. Another favorable circumstance is that, having all his time for himself, he will do more muscular exercise, which, as we know, decreases glycosuria (either by walking or undergoing a regular course of the now well-known Zander treatment, nearly all the famous spas having elaborate Zander institutes). And last, but not least, it is a well-known fact that the alkaline-sulphatic and alkaline-muriatic waters of some spas have a good influence not only on diabetes but also on gout, which we find so often combined with diabetes, and on oxaluria, another complication not seldom found. In many other cases, especially of the neurasthenic type, it will be better to send the patient simply either to the seaside or to highly situated bracing places—to places where he can find enough accommodation to follow the diet prescribed.

Associated Frontal Sinus and Mastoid Disease.—T. J. Harris reports the case of a South American boy, aged seventeen years, who some months before coming under observation had had a mastoid operation done. Recurrence of symptoms led to the performance by Harris of a Schwartze operation, from which recovery had begun when the patient began to complain of pain over the frontal sinus. Catheterization of the latter relieved the pain, but did not evacuate any pus. There was a continual purulent discharge from the right naris. Suddenly there developed intense pain in the forehead, which was rebellious to all forms of treatment. The frontal sinus was opened by Luc's method without relief. The pains grew even worse, and a typhoid state developed. Finally the boy began to improve on the iodide, but pain then returned in the mastoid. This was reopened, this time by the Stacke method, and much diseased bone removed. This relieved the pain, and convalescence was uninterrupted. No history of syphilis could be elicited.—*The Laryngoscope*, April, 1900.

A Report on the Question of Contagiousness of Pulmonary Consumption.—Johann Flintermann finds that in the city of Detroit, from July 1, 1894, to June 30, 1895, one-fifth of all cases of death were due to tuberculosis. The last report shows an increase in the mortality. In New York City, in 1896, there were 35,000 deaths, and 6,000 of these were due to tuberculosis. Professor von Leyden estimates that in Germany 1,300,000 persons suffer from tuberculosis, and 180,000 die every year from this disease. The author urges education of school children and people in general as to the nature of the disease and the evils of promiscuous expectoration. House disinfection should follow death from tuberculosis. Houses, hospitals, all public institutions should be under close observation, and cases of tuberculosis isolated. Hospitals for tuberculous patients should be provided. The author does not approve of compulsory notification, and agrees with Cornet's doctrine, "The consumptive in himself is almost absolutely harmless, and only becomes harmful through his habits."—*The Physician and Surgeon*, March, 1900.

New York, May 12, 1900.

MALARIA AND MOSQUITOS.

MALARIA in its several forms constitutes perhaps the greatest obstacle to a successful colonization of the tropics. There are of course other diseases common to those regions which occasion great loss of life, but these chiefly affect the natives and can be usually controlled by intelligent prophylactic measures. The malarial fevers are by far the most deadly of the tropical maladies in both white man and native. Large parts of India are devastated and rendered valueless by this scourge, and immense tracts of land in Africa and South America cannot be inhabited by the white race without almost inevitably fatal results. The problem of the causation of malaria, which has been the despair of scientists for generations, would appear to be daily drawing nearer and nearer to its final solution. The large majority of scientific men throughout the world have virtually accepted as decisive the theory that it is mainly if not wholly by the agency of the genus Anopheles, of the mosquito family, that malarial fevers originate and are spread. In fact by many this is no longer looked upon as a theory, but as a doctrine.

A number of investigators have had a share in the discovery that the mosquito plays an important part in causing and disseminating malaria, but to Manson and Ross is generally conceded the honor of bringing the matter to its present advanced stage. Although Americans have not specially distinguished themselves in these investigations, it should not be forgotten, as was pointed out in the London *Lancet*, February 11, 1899, that A. F. A. King, at the meeting of the Philosophical Society of Washington, D. C., held on February 10, 1883, read a paper entitled "The Prevention of Malarial Fevers," in which he suggested the likelihood of marsh fevers being produced by the bites of proboscidian insects, notably in this and some other countries by mosquito bites. This, we believe, was the first occasion upon which the theory was publicly mooted.

Great activity is now being displayed in Europe with the object of deciding the question beyond cavil. For years the Italian investigators have been performing splendid service in the endeavor to probe the malaria mystery, and probably their researches have done more toward its elucidation so far than has the work of any other school. Since the establishment of the two schools of tropical medicine in Great Britain a vivid and practical interest has been taken in that country in the diseases of the tropics in general, and of malaria in particular. The British government in conjunction with the Royal Society first despatched a scientific commission to the west coast of Africa for the purpose of attempting to find the malaria-bearing mosquito, and to locate its breeding-places. Shortly after this the Liverpool School of Tropical Medicine equipped and sent out at its own expense an expedition under the leadership of Major Ross to the east coast with a similar end in view. Major Ross and his coadjutors succeeded in discovering the mosquito Anopheles claviger, and in a few instances in determining the situation of its breeding-places. The London School of Tropical Medicine, authorized by the British Colonial Office, has just sent two of its members, Drs. Sambon and Lowe, to the Roman Campagna, there to conduct certain experiments which, if terminating favorably, should convince the most sceptical that the mosquito is the dominating factor in the causation of malaria. It may be said that experiments of a like nature have already been prosecuted by the Italians Celli and Grassi, with most satisfactory results. If, then, it be taken as proved that malaria is caused by mosquitos—and the evidence in support of this contention is so strong as to appear almost unassailable—and when it is further considered that the malady is conveyed by but one species of mosquito, it follows as a natural sequence that by a wholesale destruction of the sinning insect the ravages of malaria will be greatly curtailed and perhaps in time altogether ended.

The Liverpool School of Tropical Medicine has recently published a book entitled "Instructions for the Prevention of Malarial Fever, for the use of Residents in Malarious Places," which is made the text of an able article in the London *Times* of a late date, and which has been transcribed in *Public Health Reports*, March. The article, after giving a short summary of what is now known of the mosquito theory of malaria, concludes as follows:

"All speculations about air, about soil, about 'malaria belts,' and the like have been rendered obsolete. There is no reason to believe that the parasite of malaria finds access to the human body through any other channel than by means of the Anopheles mosquito, or that 'gnats' or 'mosquitos' which infest regions free from malaria are examples of Anopheles. If this particular insect could be extirpated, there is every justification for the hope that malarious fevers would disappear from the earth; and fortunately the extirpation does not seem likely to present any insurmountable difficulty. The eggs are laid in water, and the larvæ when hatched live in water for about a week before they assume the mosquito form. As larvæ, like those of the common gnat, they rise to the surface to breathe, and a film of oil on the surface is speedily fatal to them by blocking up their air spiracles. The fully-formed mosquito lives for many weeks, but is not presumed to travel far, and probably always obtains its food within easy reach of its native pool of water, to which it periodically returns for the purpose of depositing its eggs. Much may be done therefore by drying up the pools in the vicinity of houses or by treating them once a week with a film of kerosene oil. Much may be done also by killing the mature insect when resting upon a wall after its meal; and it is to be noted that the true Anopheles rests with its body almost at right angles to the surface of the wall, while the absolutely or comparatively harmless gnat rests with its body parallel to the wall or even somewhat inclining to it."

It is devoutly to be hoped that these sanguine expectations may be realized to their fullest extent, and that the time may be in sight when malaria will be swept away.

AN ABSURD CLAIM AND A UNIQUE EXHIBIT.

In the New York *Times* of April 29th, Mr. Goodwin Brown, an Albany lawyer, claims to be the originator of "the system of public baths," which promises to become an enormous sanitary factor in our tenement life.

In our issue of December 6, 1890, we referred to the subject of public baths, and wrote: "Much credit is due to Dr. S. Baruch, of this city, for his earnest agitation of the subject." Since that time we have frequently alluded to the free-bath movement inaugurated by this gentleman. Before medical and philanthropic societies the doctor urged the sanitary importance of the rain bath, and he succeeded in so imbuing Dr. Gertrude Wellington, of Chicago, with his views that she secured the construction of the Carter Harrison Baths in 1894, and of four other baths since that time.

Failing to overcome the opposition of Mayors Grant and Gilroy, the doctor found an earnest and able coadjutor in Mr. Goodwin Brown, who in 1895 brought about the passage of a mandatory act, in obedience to which several free baths have been and are now being constructed in this State (one city being compelled by a supreme court mandamus to build a bath).

While, therefore, Mr. Brown deserves credit for aiding Dr. Baruch in this important enterprise, his sweeping claim is absurd. Mr. Brown relates that "he was attracted in 1891 to the new method of bathing adopted in the soldiers' barracks in Berlin." It is singular that he had to go so far for this important information, when Dr. Baruch had explained the rain bath in 1890 to the Academy of Medicine, and the prominent New York dailies had referred to it as a matter of great public interest, and the New York Juvenile Asylum already had constructed a rain bath. We believe that we voice the sentiment of the medical profession in defending one of its members against encroachment, and insisting that credit be not withheld from the man who has so valiantly and successfully made the fight for this great sanitary boon.

We are gratified to learn that an exhibit in the department of social science and hygiene of the Paris exhibition will demonstrate to the world at large the feasibility, economy, and perfection of the system of public baths so ardently and successfully advocated by Dr. Simon Baruch. It is a matter of pride that this is the only country in the world which possesses public baths furnishing at all seasons warm water, soap, and towels free to any one, and that this great boon to the poor is the result of persistent endeavor of a medical man.

THE AMATEUR NURSE IN SOUTH AFRICA.

There has been within the past few weeks a rush of female members of the British aristocratic and plutocratic circles who have become infected with the disease now known as khaki fever, to Cape Town. So great indeed has been the influx of society women to that already overcrowded city, that Sir Alfred Milner, the governor-general of the South African British possessions, has deemed it necessary to protest against this invasion, and gravely to warn these ladies that not only are they themselves running into needless danger, but that their presence is inadvisable for general sanitary reasons, as well as being an additional embarrassment to the authorities. Lord Roberts concurs in this expression of opinion.

A banquet was given at the Reform Club in London on Saturday, April 28th, the guests of the evening being Sir William MacCormac and Mr. Frederick Treves, both of whom have recently returned to England after fulfilling their duties as consulting surgeons to the British forces at the front. The latter gentleman, who is reputed to be almost as able a speaker as he is operator and writer, delivered an incisive speech, laying bare what he esteems one of the most objectionable features of the present war. Referring to the amateur nurses who have gathered in such numbers in Cape Town and in some other parts of South Africa, he spoke as follows: "So far as the sick are concerned there are only two plagues in South Africa—the plague of flies and the plague of women. The flies we get rid of by horsehair wisps and other appliances, and the flies at least depart at night. But the women are absolutely and really a terror. They come out in the guise of amateur nurses, after having exhausted every other form of excitement. Considering that we are engaged in war the number of well-dressed ladies at Cape Town and elsewhere giving picnics is a blot on the campaign." Doubtless some of these ladies are guided solely by patriotic and humane sentiments, but it is to be feared that in the majority of instances Mr. Treves' pungent criticisms are well warranted, and that a very large proportion are impelled by the failings common to the daughters of Eve and by an insatiable desire not to be outvied by any of their compeers. It is extraordinary, too, to notice, so implicit is the belief of the everyday woman in her powers as a nurse, that it is impossible to convince her that in order to carry out efficiently the onerous duties of an army nurse some training is necessary in addition to the possession of a certain amount of mental and physical fitness. However, the question of women as army nurses has been of late considered at sufficient length in the MEDICAL RECORD, and we can only say that if, over and above the trials incidental to the life of an army doctor in time of war, he is expected also to cope with a multitude of society women posing "in the guise of nurses," he is certainly deserving of heartfelt sympathy.

SMALLPOX IN THE PHILIPPINES.

IT is a somewhat curious fact that when, as now, both plague and smallpox are prevalent in the Philippines, and fifty thousand American soldiers or thereabouts are in those islands, but small heed is paid in either medical or lay journals to the presence of these diseases. It is true, as was pointed out in an article by Maj. C. F. Mason, M.D., U.S.A., published in the MEDICAL RECORD some few months ago, that smallpox is universal throughout the islands among all classes of the natives, and is consequently regarded as a matter of course. It is also true that the efficacy of vaccination as a preventive of smallpox has already received further convincing proof among the United States troops campaigning there. Nevertheless it is a matter for some surprise that the medical profession of this country evinces a certain lack of interest in the diseases of the Philippines.

The London *Journal of Tropical Medicine* for April publishes an editorial entitled "Smallpox in the Philippines," in which, after briefly referring to the article by Major Mason mentioned above, it goes on to give a short history of the progress of vaccination in the Philippines and in the East generally. The writer of the editorial in question points out that vaccination was introduced into the Philippines by the Spanish about the beginning of the nineteenth century, and draws attention to the difficulties experienced until quite recent times in procuring effective lymph, owing to its deterioration in transit. The editorial in the *Journal of Tropical Medicine* concludes as follows: "It is satisfactory to know that the far East is better supplied with vaccine lymph than it was ten years ago, when all lymph came from Britain or America. The lymph from Britain, owing to the voyage through the tropics, was often useless; but now there is a vaccine institution at Hong Kong; and from Japan, Saigon, Calcutta, and even Sumatra and Java, lymph is sent to China and the Philippines. Seeing the unprotected state of the natives in the Philippines no doubt the Americans will soon establish vaccine institutes in Manila and elsewhere in the Philippines, and endeavor to induce the ignorant and prejudiced natives to protect themselves against smallpox, without doubt the greatest scourge known in the far East."

The Rhode Island Hospital.—On May 2d the new southwest pavilion of the Rhode Island Hospital was opened with appropriate ceremonies, and on May 10th the bacteriological laboratories in the same pavilion were opened. On the latter occasion addresses were made by Drs. W. T. Councilman, J. W. C. Ely, and G. Alder Blumer.

News of the Week.

Dr. Jacobi's Birthday. — The seventieth anniversary of the birth of Dr. A. Jacobi, of this city, was celebrated at a banquet held last Saturday night at Delmonico's, which was attended by more than four hundred of his friends and professional associates. His birthday was on Sunday, May 6th, but his friends were too impatient in their desire to congratulate him to wait. The speech-making was begun early, but at the stroke of midnight all rose and drank to the health and long life of the guest of honor. Dr. Joseph D. Bryant presided, and speeches were made by Mr. Carl Schurz on "Dr. Jacobi as a Citizen," Dr. William H. Thomson on "Dr. Jacobi as a Physician," Dr. William Osler on "Dr. Jacobi as a Scientist," and President Seth Low of Columbia University on "Dr. Jacobi in Relation to Medical Education." A poem in honor of Dr. Jacobi's life and works, by Dr. S. Weir Mitchell, was read, and Dr. A. G. Gerster presented the guests with a copy of the "Festschrift," which contains contributions from fifty-three medical men of eleven nations. In his reply Dr. Jacobi said he wished he could proceed from man to man and in silence press their hands, for words did not suffice for the throng of feelings that swelled his heart. He reviewed the events and changes that had taken place in medicine during the nearly half-century that he had lived and practised in this country. Closing, he said that he did agree with some in believing that the moral tone of the profession has been lowered in these latter days when the spirit of trade is paramount. There have been jealousy, strife, and competition at all times, and medical men, like other men, are always human. The "good old times" is an ideal that, while its consummation is too far ahead or beyond the horizon altogether, is searched for backward. Doctors are now, as they have always been, what their time, their people, their surroundings make them. On Sunday the board of directors of Mt. Sinai Hospital presented him with a silver tankard bearing the following inscription: "To Dr. Abraham Jacobi, on the seventieth anniversary of his birthday, from the Mt. Sinai Hospital, in grateful recognition of forty years of devotion and fidelity, May 6, 1900."

Manuel Garcia, the inventor of the laryngoscope, celebrated in London, on March 17th, the ninety-fifth anniversary of his birth. He was born in Madrid, March 17, 1805. When he was a lad of seven, the family went to Naples. He had a fancy for the sea, but, in deference to his parents' wishes, studied for the operatic stage. His earliest appearance was in New York, where he was the *Figaro* of the first performance of "Il Barbiere" in North America. His physique was, however, too delicate for the exacting work of the stage, and returning to Europe he established himself at Paris as a singing-master, later on becoming a professor at the Conservatoire. Since 1850 he has resided in London. His demonstration of the laryngoscope was made before the Royal Society of London, in 1855, in a paper entitled "Physiological Observations on the Human Voice." The full significance of his discovery was not at first appreciated in England, but it was taken up and developed by Turck and Czermak in Austria.

The Hospital Ship "Maine" sailed from Southampton on her return voyage to the Cape on May 3d.

The Plague is reported to have appeared at Suakim in Egypt, and Malta has declared a quarantine of twelve days against all passengers from that country.

Cholera in India.—It is reported from Bombay that cholera is alarmingly virulent among the natives at the famine relief works, where there are fifty deaths daily from the disease.

The Late Drs. Mulheron, Eastman, and McFarland.—At a special meeting of the Broome County Medical Society, held at Binghamton, May 1st, resolutions were adopted regarding the recent deaths of Drs. Edward Mulheron, C. C. Eastman, first assistant physician of the Binghamton State Hospital, and S. F. McFarland.

Medical Missions.—One of the sessions of the Ecumenical Missionary Conference, recently held in this city, was devoted to a discussion of medical missions. Papers were presented by Drs. George E. Post, professor of surgery in the Syrian Protestant College at Beyrout; C. F. Harford-Battersby, of Lokoja, River Niger, West Africa; F. Howard Taylor, of the China Inland Mission; and O. R. Avison, of Seoul, Korea. Dr. Post said that the first aim of medical missions should be the relief of suffering from motives of brotherhood, and they can be planted where no other branch of evangelical work is possible, for they are founded on a need which is universal and felt by all. Every human being is sometimes ill, and, when not ill himself, may be anxious on account of the illness of some relative or friend. The physician therefore has immediate and welcome access to vast numbers who will not have any intercourse with other missionaries. "Missions of every Christian nation," he said, "have by an unerring instinct established and developed medical work, and every year sees a wider extension of its sphere and usefulness. Worldly people, who look askance at other forms of mission work, applaud medical missions and give of their substance to sustain them. Kings and rulers in Mohammedan and heathen lands have built hospitals and given means for their endowment. Far out on the picket line of evangelism heroic men and women gather around them such crowds as collected on the pathways where Christ was wont to walk. Fearless of death, they grapple with cholera, plague, leprosy, smallpox, scarlet fever, diphtheria, and other contagious diseases. In the tainted atmosphere of the dispensary they toil hour after hour to relieve the mass of misery. They go late to sleep, and often rise a great while before day to watch the crises of disease and operation. They remain in sultry, fever-stricken cities of the coast during the long tropical summer, if haply they save some of God's poor. They travel under the burning sun or through blinding storms to reach new centres and open up the way for a further extension of the work. The church which sends them knows the value of that work. The sick whom they cure have given proof of it." Dr. C. F. Harford-Battersby spoke of the possibilities of the missionaries of the future. He declared that the home boards should see to it that they sent only such men and women to the medical posts as were thoroughly fitted, and that no greater damage could be inflicted upon the work abroad than by sending out incompetent medical men. He insisted that the physicians should be earnest Christians, but argued against the idea that missionary doctors should be ordained ministers. He said a man should not be compelled to bear the worry and anxiety of both a medical and a mission station. Dr. F. Howard Taylor, of China, emphasized the need of both spiritual and physical qualifications. In speaking of the need of more medical missionaries, he said that he was the only doctor among twenty millions of natives. He spoke of the physical qualifications of the missionaries and said only men and women of sound body and mind were wanted. "We must have men of sound mind," he said. "We cannot use cranks, and as for men with fads, they had better remain where old fads pass and new fads appear, for in China we have no fads." Dr. Avison said that physicians are sent to the mission fields, first, to give medical care to the missionaries; second, to render that practical help to the sick natives which must always be extended by Christians to those in trouble; third, as a means of advancing evangelistic work by disarming prejudice and bringing the Gospel to the notice of many who, but for the evident benefits to be gained from the former, would decline to put themselves within reach of the latter; fourth, to train native physicians and nurses and prepare them to carry on the beneficent work which the missionaries have inaugurated. Other speakers were Dr. Franklin Pierce Lynch, of Congo; Dr. Frank Van Allen, of India; and Dr. Hepburn, the first American missionary to go to Japan, who went to the East as a medical missionary sixty years ago.

American Dermatological Association.—At the meeting just held in Washington the following officers were elected: *President*, Dr. F. J. Shepherd, of Montreal; *Vice-President*, Dr. D. W. Montgomery, of San Francisco; *Secretary*, Dr. F. H. Montgomery, of Chicago. New members elected were Drs. C. J. White, of Boston, and O. H. Holder, of New York. The next meeting will be held in Chicago in June, 1901.

A Test of the Mosquito Theory of Malaria.—On June 1st Drs. Sambon and Low, of the London School of Tropical Medicine, will begin a summer residence in a place in the Roman Campagna where æstivo-autumnal malarial fever is most prevalent. They will live in a small wooden building with windows and doors protected with wire screens, which will also be placed under the eaves and over the chimney opening. During the daytime, when the Anopheles, or malaria mosquito, does not bite, they will go about at will, but from a little before sundown to some time after sunrise they will keep strictly within doors, although still exposed to the air and soil emanations. Their drinking-water will be the same as that used by other residents of the Campagna, and in fact all their conditions of living will be the same, save only that they will be preserved from the stings of the night mosquitos.

The Society of the Alumni of the Sloane Maternity Hospital.—At the third annual dinner of this society, on Friday, April 27th, the following officers were elected: *President*, Dr. Samuel M. Brickner; *Vice-Presidents*, Drs. J. S. Waterman and L. A. di Zerega; *Recording Secretary*, Dr. L. E. La Fétra; *Corresponding Secretary*, Dr. H. S. Carter; *Treasurer*, Dr. W. V. V. Hayes; *Pathologist*, Dr. James Ewing.

Convention of Trained Nurses.—The third annual convention of the alumnæ of the training-schools for nurses of the United States and Canada was held on Thursday, Friday, and Saturday of last week at the Academy of Medicine in this city. About two hundred delegates were present. The president of the alumnæ was Mrs. Hunter Rodd. The address of welcome was delivered by Mrs. Cadwalader Jones.

Dentists for the Army.—There is now before the House of Representatives a bill to authorize the appointment to the army, under regulations to be prescribed by the surgeon-general, of dental surgeons to be attached to the different branches of the service, in the same manner that medical officers are now provided. The necessity for dentists in the army was manifested during the Spanish war and still more during the Tagal insurrection. The bill was recommended for speedy passage by the House committee on military affairs over two months ago, and although it has been on the calendar ever since it was reported, for some reason it has never been acted upon. The measure has the indorsement of army officers, dentists, and physicians throughout the country.

Tonsorial Antisepsis in Boston.—The board of health of Boston has issued an order enforcing cleanliness in barber shops in that city, its provisions being that "the place of business of all barber shops, together with all the furniture, shall be kept at all times in a cleanly condition. Mugs, shaving-brushes, and razors shall be sterilized by immersion in boiling water after each separate use thereof. A separate clean towel shall be used for each person. Alum or other material used to stop the flow of blood shall be used only in powdered form and applied on a towel. The use of powder puffs is prohibited. Every barber shop shall be provided with running hot and cold water. No person shall be allowed to use any barber shop as a dormitory. Every barber shall thoroughly cleanse his hands after serving each customer."

American Therapeutic Society.—In pursuance with a call for an American Therapeutic Society, issued by the Therapeutic Society of the District of Columbia, a meeting was held in Washington, May 1, 1900. The organization was effected and much enthusiasm displayed. The following were chosen as officers of the new society, which will become affiliated with the Congress of American Physicians and Surgeons, which meets in Washington every three years: *President*, Dr. Horatio C. Wood, of Philadelphia; *First Vice-President*, Dr. Howard H. Barker, of Washington; *Second Vice-President*, Dr. R. W. Wilcox, of New York; *Third Vice-President*, Dr. E. H. Long, of Buffalo; *Secretary*, Dr. Noble P. Barnes, of Washington; *Recorder*, Dr. William M. Sprigg, of Washington; *Treasurer*, Dr. John S. McLain, of Washington. The meetings of the American Therapeutic Society will be held annually; the next meeting being in Washington, D. C., on May 7, 1901.

Quarantine against Yellow-Fever Ports.—On May 1st the usual summer quarantine regulations went into effect at the port of New York. All passengers who cannot show certificates of immunity are to be detained at Hoffman Island under observation until five full days have elapsed since they left Havana or other yellow-fever port.

The International Dermatological Congress.—At the meeting of the American Dermatological Association, held in Washington in connection with the Congress of American Physicians and Surgeons, a committee was appointed consisting of Drs. J. Nevins Hyde of Chicago, Henry W. Stelwagon of Philadelphia, and T. Caspar Gilchrist of Baltimore, to represent the association at the International Dermatological Congress, to be held in Paris in early August, and to extend a warm invitation, in the name of the association, to the members of the congress to hold the next international meeting in this country, in New York. The committee was further instructed, in the event of the congress giving favorable response, to present the name, and urge the election, of Prof. James C. White, of Boston, the first president of the American Dermatological Association and an honorary member of the French and Italian dermatological societies, for the presidency of that congress.

College of Physicians of Philadelphia.—At a special meeting of the section on gynæcology held April 30th, Dr. Henry J. Garrigues, of New York, read a paper entitled "Periods in Gynæcology." At the conclusion of the meeting a reception was tendered Dr. Garrigues at the University Club. At a stated meeting held May 2d, Dr. J. C. Gittings read for Dr. James Ely Talley a paper entitled "Angio-neurotic Œdema of the Salivary Glands."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C., May 5, 1900.—Changes in the medical corps of the United States navy for the week ending May 5, 1900. April 27th (by cable from Asiatic station).—Assistant Surgeon W. E. High detached from the *Manila* and ordered to the hospital. Assistant Surgeon D. G. Beebe detached from the *Yorktown* and ordered to the *Isla de Luzon*. April 30th.—Surgeon T. A. Berryhill detached from the *Monongahela* on reporting of relief, and ordered home and to wait orders. Passed Assistant Surgeon W. M. Wheeler detached from the *Vermont* May 3d, and ordered to the *Kearsarge*. Passed Assistant Surgeon

G. H. Barber detached from the *Kearsarge* and ordered to the *Monongahela*. Assistant Surgeon D. H. Morgan ordered to the *Vermont* May 3d. May 3d.—Medical Inspector J. C. Boyd detached from duty as assistant to bureau of medicine and surgery, Navy Department, and ordered to the *New York* as fleet surgeon of the North Atlantic station. Medical Inspector P. Fitzsimons detached from the *New York* as fleet surgeon of the North Atlantic station, and ordered to proceed home and wait orders. Surgeon J. D. Gatewood detached from the bureau of medicine and surgery, Navy Department, May 8th, and ordered to duty as assistant to bureau of medicine and surgery, same day. Passed Assistant Surgeon C. D. Brownell ordered to the naval training-station, Newport, R. I.

Obituary Notes.—DR. GEORGE FULNER, of Mechanicsburg, Pa., died on May 1st, at the age of seventy-five years. He was a graduate of the Jefferson Medical College in 1853.

DR. JOHN STOCKTON HOUGH, once a practising physician in Philadelpiha, later a resident of Paris and London, and for the last dozen years a gentleman farmer at Ewingville, near Trenton, N. J., died on May 6th, as the result of injuries sustained in being thrown from his carriage by a runaway horse.

DR. EDWARD E. VINCENT, who was surgeon in Peary's expedition to the arctic regions in 1893, was killed in Detroit on May 4th. He was on a bicycle, and in trying to escape from a buggy which was bearing down on him he was thrown under a rapidly moving trolley car.

Obituary.

LANDON CARTER GRAY, M.D.,

NEW YORK.

DR. LANDON CARTER GRAY died at his home in this city on Tuesday, May 8th, after a long illness. He was born in New York City on April 3, 1850. While in Columbia College he had serious trouble with his eyes, on which account he went abroad for a rest, and upon recovering he remained there, studying at the University of Heidelberg. Later he returned to this city and studied medicine, taking his degree from the Bellevue Hospital Medical College in 1873. After practising for a while here he removed to Brooklyn, where he remained until 1886.

Dr. Gray early turned his attention to the study of diseases of the nervous system, and speedily won for himself an enviable reputation in that line of practice. While in Brooklyn he was professor of neurology at the Long Island College Hospital Medical School, and was visiting neurologist to St. Mary's Hospital. He was one of the founders of the New York Polyclinic, and was the first occupant of the chair of nervous and mental diseases in that institution. He was at various times president of the Medical Society of the County of New York, the American Neurological Association, the New York Neurological Society, and the Society of Medical Jurisprudence, and was for many years chairman of the executive committee of the Congress of American Physicians and Surgeons. He was the author of a work on nervous and mental diseases, and was at one time a frequent contributor to periodical literature in this specialty.

Progress of Medical Science.

New York Medical Journal, May 5, 1900.

An Appeal for Systematic Treatment of the Consumptive Poor.—J. F. Russell advances the following propositions: That a large number of poor people suffering with pulmonary tuberculosis in a curable condition cannot go to sanatoria for treatment; that dispensary treatment is practicable, successful, and comparatively inexpensive; that curable pulmonary tuberculosis by dispensary treatment is confined to the early stage; that without organized effort such cases are difficult to attract for treatment, owing largely to ignorance of the disease and a belief that it is incurable; that the treatment covers a long period and patients require daily supervision; that the majority of dispensaries at present make no adequate provision for such treatment: that it is the duty of such dispensaries to organize classes for this purpose. The advantages to be derived from the general adoption of the plan of treatment outlined are as follows: Many are cured; all are benefited; all are educated and made capable of protecting and teaching others; all, laboring and idle alike, can come for treatment. In the end it will break down the deep-rooted belief that pulmonary tuberculosis in all stages or any stage is incurable, and lead to the application for relief early in the disease.

Management of the Hair during and after Fevers.—G. T. Jackson advises the careful combing of the hair during acute febrile conditions. The use of the fingers, if the brush is inadmissible, will prevent much of the snarling so often met with. He advises against cutting the hair and particularly against shaving the scalp. Only diseased hair will come out under the usual manipulations. Once or twice weekly we may use a pomade of a drachm of precipitated sulphur in one ounce of cold cream. This should be carefully worked into the scalp. Once in two or three weeks a shampoo may be given, and for this purpose the tincture of green soap is best. Just as little of the soap should be used as will make a good lather. A hose from the bath-room faucet should be used to wash the soap out. Pomade is then to be rubbed in.

Practical Points in Ether Anæsthesia.—C. F. Burrows advocates giving half an ounce of magnesium sulphate twelve hours before anæsthesia, with a rectal washing one hour before with a quart of warm water. Only milk should be given during this period, and nothing at all during the last four hours. Water may be used freely, but the bladder should be empty just before the ether is begun. He is opposed to the usual morphine and atropine injection. The rest of the article is an enumeration of the customary precautions agreed to by all anæsthetists.

Journal of the American Med. Ass'n, May 5, 1900.

Surgery of the Fifth Nerve for Tic Douloureux.—R. Abbe gives his experience with twenty cases, the Hartley operation being done five times, the Salzer four, and the Carnochan eleven. He advocates a thoroughly done Carnochan operation, with clean resection of the second branch to the foramen rotundum, for most bad cases, even when the first and third branches seem to share the neuralgic shocks. If one chooses to do the Salzer, then he advises a section of the zygoma turned down with skin, and a muscle splitting of the temporal rather than coronoid section. If the intracranial method is adopted, he advocates the simple section and limited excision of the second and third branches from the Gasserian ganglia to the foramina, and interposition of a piece of sterile rubber tissue. He sees no reason for believing that the resection of the Gasserian ganglion is necessary to the thorough severance of nerve connection with the brain. In most cases of inveterate tic a chronic neuritis exists, usually of the middle branch. Hence the quick and permanent cures which we are able to record by excisions anterior to the Gasserian ganglion.

The Early Diagnosis of Pulmonary Tuberculosis.—E. F. Wells does not recognize a pretuberculous stage. The disease is often preceded by anæmia, gastric and intestinal disorders, but such states are purely accidental and not premonitory. The beginning of the attack must be coincident with the implantation and parasitic development of the bacillus of tuberculosis. Special attention must be given to the possible occurrence of cough, expectoration, hæmoptysis, thoracic tenderness, fever curve, gastric symptoms, nutrition, blood changes, and pulse characteristics. Tuberculin may be used, but a negative result with this agent is also of value, for it enables us to affirm that not only is the suspected pulmonary affection not tuberculous but that there are no latent pulmonary foci and that tuberculosis does not exist in other parts of the body. In a doubtful case the *x*-ray may tip the balance for or against the probability of tuberculosis being present. This is especially true when thoracic soreness or pain is present, the *x*-ray revealing restricted movement of the diaphragm upon the affected side.

Natural History of Tic Douloureux, with Remarks on Treatment.—C. L. Dana gives a table showing the duration and treatment of forty-two cases. He believes that the early forms, such as he calls a "migrainous tic," occurring usually in women, should not be operated on. There are some exceptions to this, however, in which tic douloureux occurs in early life, due to a distinct local disease, such as an inflammation of the nerve, or of the antrum, or of the jaws. In true tic of the degenerative period of life, prompt medical treatment will usually control the disease and operation is rarely indicated at first. In tic which has lasted three or more years, it may be safely said to the patient that medical treatment may produce a remission, and that this remission may be repeated, and that eventually the disease may be controlled by repeated treatments, but this is not at all sure. It may be said here too that a minor operation may give more relief than medical treatment. The question of prescribing major operations must be decided in each individual case, on its special merits.

Further Observations on the Treatment of the Abdominal Viscera through the Colon.—F. B. Turck describes the method of forcing hot or cold air into the bowel, a double tube allowing of escape. This hot-and-cold-air plan through its stimulant power produces what may be styled "gymnastics of the colon." By other methods he executes massage of the colon, secures colonic electrization, effects direct medication of the colon, and also introduces alimentary substances. The varieties of tubes employed are figured in the original article. Turck considers colonic lavage to be of especial service in typhoid fever. While the length of the disease remains the same, there is a marked diminution in the lassitude, delirium, pyrexia, and other constitutional expressions of the typhoid poison.

The Medical School of the Future.—H. P. Bowditch sums his conclusions as follows: (1) A medical school of the first rank will, in the immediate future, be connected with a university, but will be independent of university control as to methods of instruction and the personnel of the teaching body. (2) It will offer advanced instruction in every department of medicine, and will therefore necessarily adopt the elective system of some sort. (3) The laboratory method of instruction will be greatly extended, although the didactic lecture will still have its place. (4) The work of the students should be so arranged that their attention will be concentrated upon one principal subject at a time. (5) Examinations will be so conducted as to afford a test both of the faithfulness with which a student performs his daily work and of his permanent acquisition of medical knowledge.

Philadelphia Medical Journal, May 5, 1900.

Some of the Physiological Methods and Means Employed by the Animal Organism in its Continual Struggle against Bacteria for Maintenance of Life and Health.—S. J. Meltzer maintains that in the struggle against bacteria the defence of the body is not carried on by any single element. Neither the body-fluids, nor the leucocytes, nor the other body-cells alone can claim exclusive merit, but each does its share. Further, in health at least, the actual defence is carried on not by a single tissue, or a single function, but by concerted action of several tissues and functions, by the working of a mechanism. As to the plan of defence the writer says the aim is to reduce greatly the number of bacteria by mechanical methods, and then to destroy the remnant by some biological means. The mechanical methods are: barricading the entrance, throwing out again the landed bacteria, or carrying them to the place of destruction. He then suggests two new factors which he believes to be capable of assisting the work of the destruction of bacteria within the body, viz., the process of plasmolysis, and the vibrating effect of the heart impulse. The conclusions are that the regular, moderate invasion of bacteria into the interior of the body, so far from being an infection—an evil—is a means of immunization; latent infection, therefore, is not a foe to normal life or health, but is rather a confederate in defence of it.

On Recent Advances in our Knowledge Concerning the Etiology of Malarial Fever.—William Sydney Thayer reviews the investigations undertaken in recent years which have resulted in the discovery of the part taken by certain mosquitos in the spread of malaria. In malarious districts around Baltimore and in Virginia and North Carolina he has found several varieties of Anopheles. As to the practical deduction from this discovery he says that there is reason to believe that if in any given region (1) proper measures for treating the spring relapses of malaria were adopted, and (2) efficient measures for destroying the dangerous mosquitos in their larval stage could be carried out, the prevalence of malaria might be materially controlled. The importance to the community of insisting upon the proper treatment of all cases of malaria cannot be too strongly emphasized, for an infected patient in a malarious district is a source of danger to those about him. Before we can attempt, however, to carry out intelligently measures to destroy the mosquitos we must first determine definitely the dangerous species of mosquitos in this country, and must study their distribution, their habits, and their breeding-places.

Case of Persistent Jaundice in which an Exploratory Operation was Performed.—E. F. Eliot operated on a patient who for four and a half years had been jaundiced. A tumor of the gall bladder could be made out through the abdomen. The gall bladder was found distended and a pint and a half of thick black gelatinous bile was drawn off. After incision the mucous lining of the organ was found covered with a gritty substance, which was scraped off and the cavity was packed with iodoform gauze. Death occurred on the sixteenth day from acute enteritis, supposed to have been caused by the gritty matter and altered bile entering the gut after so long a period of freedom from bile.

The Pathology and Treatment of Pneumonia.—Nathan Raw considers pneumonia a self-limited disease, which can neither be aborted nor cut short by any known means. It may terminate favorably without medicines; still an immense amount of good can be done by the physician. It is essential to control the fever by sponging with iced water. Cardiac failure is the great stumbling-block. Here alcohol should be given up to twelve ounces of good brandy in twenty-four hours. In the majority of cases alcohol is not required in pneumonia. Strychnine up to $\frac{1}{12}$ grain hypodermatically will often have a miraculous effect upon the heart. The author's experience with oxygen in sixty-five cases has not been favorable. Saline injections are still in the trial stage.

Myotonia Congenita. — Leonard Guthrie reports the case of a boy aged ten and one-half years, who for a year had presented symptoms. The thumbs were turned in and a tonic spasm of the hands resembled that of tetany. The grasp of objects was slow and awkward and he could not let go quickly. The spasm was more marked after rest. The gait was jerky, and he did not bring his heels fully to the ground. Running was easier than walking. Tonic contraction persisted during sleep.

The Pathology of Acute Myelitis.—Mayer relates the history of seven cases in which the microscope showed degeneration of the white and gray substance of the cord. The differences in appearance between the "perforated" and "infiltration" forms are given.

British Medical Journal, April 28, 1900.

Inoculation with Typhoid Vaccine as a Preventive of Typhoid Fever.—R. W. Marsden reports an experiment with the typhoid vaccine in the Monsall Hospital, Manchester. Of the twenty-two nurses in the hospital, fourteen were vaccinated, four had had typhoid fever, and four refused to submit to the experiment. During previous seasons the number of nurses who were attacked with the disease was: 1895–96, three; 1896–97, two; 1897–98, eight; 1898–99, six; during the season of 1899–1900 following the vaccinations none of the nurses suffered an attack. One of the nurses had an ephemeral fever in January, lasting only a few days. Assuming that this ephemeral fever was a genuine attack of typhoid, the author thinks its very mildness and evanescent nature would speak strongly for the contention that there is "an increased power of resisting infection by living typhoid bacilli," and certainly the occurrence of such attacks would never be a cause of anxiety.

A Family with Addison's Disease.—Robert A. Fleming and James Miller report five cases of an affection presenting all the clinical features of Addison's disease, occurring in a woman and her four children, aged from two and a half to seven years. The mother, a woman twenty-eight years old, showed all the typical clinical features, including pigmentation of the mucous membrane of the mouth and lips, while the children, in order of age, demonstrated the same phenomena in decreasing severity and distinctness. The moles, placed so prominently in the list of important clinical features by Addison, Greenhowe, and others, were specially characteristic of this family group.

Antityphoid Vaccine.—T. Wilson says that his experience of the use of the antityphoid serum of Professor Wright, of Netley, among troops in South Africa, is that if it does not render the typhoid bacilli innocuous, it at least will modify favorably an attack of typhoid fever. Before making inoculations he had the men abstain from alcohol for three days and take an aperient on the morning of the fourth day, and on the morning of the fifth day be inoculated.

The Lancet, April 28, 1900.

A Case of Pernicious Anæmia Treated by Anti-Streptococcic Serum.—The treatment of a case is thus described by W. Elder: the patient, a man aged thirty-five years, was admitted to hospital February 3d, and commencing one week later his mouth was thoroughly washed and brushed with an antiseptic mouth-wash and he was given gr. v. of salol and gr. xv. of salicylate of bismuth internally every six hours. Gr. x. of anti-streptococcic serum was at first injected into the subcutaneous tissue over the dorsum ilii every second day. At the first two injections, on account of a fault in the syringe, he received only about 8 c.c., but afterward 10 c.c. was given on each occasion except on February 9th, when he got only 5 c.c. From February 3d till March 19th he received in all eighteen injections of the serum, and the antiseptic treatment was continued all through. With the exception of a hypnotic occasionally when his nervous symptoms required it, and a dose of castor oil or cascara sagrada for his constipation, this was the only medicinal treatment. He got none of the usual remedies for anæmia—neither iron nor arsenic nor bone marrow. On March 20th (fifty-two days after his admission and forty-five days after the commencement of treatment) his blood had practically reached normal.

Strychnine as a Factor in Causing Cerebral Hemorrhage.—L. Grant sounds a note of warning against the very prevalent practice of the public, which consists in taking, whenever a feeling of depression is felt, patent nostrums or even officinal preparations which contain strychnine. This drug is a cardiac, vasomotor, and gastric stimulant, and may so brace the system as to lead one to overwork. Moreover, it may show a cumulative action. All of these effects combine to bring an unusually severe strain on the vessels, and in patients who are the least atheromatous may be the cause of some vascular break-down. A case of apoplexy narrated by Grant tends to support this view. This particular patient was in the habit of taking syrup of the phosphates of iron, quinine, and strychnine, together with bicarbonate of soda for a morning "fizzing" drink.

On Cysts of the Breast; their Relative Frequency, Diagnosis, and Treatment.—From a careful analysis of two hundred and forty-two cases of breast disease, T. Bryant has come to the following conclusions: Cysts of the breasts are far more common than they are generally believed to be. They are chiefly found in women during the same period of life as that in which cancer is met with; they are mostly quite amenable to local treatment without the sacrifice of the breast gland in which they are situated. There is no reason to believe that women who have these cysts are more prone to cancer than those who have them not. The article is an elaboration along the lines indicated by the foregoing propositions.

An Experimental Inquiry into Scurvy.—F. G. Jackson and V. Harley believe that the view requires modification which attributes scurvy to the effect of want of fresh vegetables or lime juice. They base their opinions upon a study of the sanitary records of various arctic expeditions and upon the results of dietetic experiments upon monkeys. They conclude that the presence of the vegetables or lime-juice is not alone sufficient for the prevention or cure of scurvy, and that we must regard the condition of the food in general, and especially the state of preservation of the meat, as the essential factor in the etiology of the disease.

On the Value of Abdominal Distention as an Indication for Exploratory Laparotomy in Intestinal Obstruction.—J. J. Waddelow reports the case of a man, aged fifty-four years, with complete intestinal obstruction lasting seven days, and fecal vomiting lasting two days. The onset of the disease took the form of an acute biliary colic, but the exact cause of the obstruction was unknown. Abdominal distention was present, but, as it did not progress, operation was deferred and reliance was placed on laxative enemata. Recovery ensued.

Inversion of the Myomatous Uterus.—By W. Roger Williams.

Endoscopy of the Œsophagus and Stomach.—By G. Kelling.

Berliner klinische Wochenschrift, April 9 and 16, 1900.

Some Exceptional Points on the Diagnosis and Therapy of Pulmonary Tuberculosis.—H. Senator enumerates in this article some of the measures which may be utilized for the relief of various symptoms. For hæmoptysis he suggests the feasibility of giving large doses of gelatin internally. This remedy has been shown to have the power of increasing the coagulability of the blood. He also commends the ligature of the limbs and inhalation of astringent agents. For the fever, he has obtained the best results with phenacetin, lactophenin, citrophen, and pyramidon. For night sweats, pencilling of the skin with formol has frequently afforded relief.

Contribution to the Apparatus Therapy in Affections of the Central Nervous System.—P. Jacob states that there are three classes of apparatus capable of employment in maladies of the central nervous system. The first class is designed to replace the function of muscles which are completely powerless; the second supports the action of muscles which are only partially disabled, while the third is designed to reinforce the action of muscles which are in themselves normal but upon which additional work is thrown owing to the incapacity of muscular congeners. Illustrative cases are given under these respective headings.

Disturbances in the Filtration Power of Diffusely Inflamed Kidneys.—G. Köresi and W. Róth-Schulz give the following conclusions, based upon their own observations: (1) In parenchymatous nephritis the filtration power of the kidneys is lessened in proportion to the severity of the case. (2) In the contracted kidney this power remains more or less normal, sometimes completely so. (3) The same holds true of the kidney of heart disease so long as compensation does not fail. (4) The congested kidney occupies in this respect a transition stage between chronic parenchymatous nephritis and the contracted kidney.

An Unusual Case of Acute Anterior Poliomyelitis of Infectious Origin Occurring in an Adult.—K. Gumpertz reports the case, which occurred in a young man aged twenty-three years, who after a slight illness of a few days, during which he complained of general malaise, dulness, anorexia, and fever, presented the typical paralytic symptoms of anterior poliomyelitis, which gradually improved in the course of the following three months. As he had been exposed to typhoid infection, it was concluded, after a careful study of all the factors in the case, that this was the nature of the infectious agent.

On the Diagnosis of Changes in the Lungs due to the Inhalation of Dust in Industrial Occupations.—Professor Bäumler calls attention to the relative frequency in some localities of an affection of the respiratory organs simulating phthisis, but which runs a rapidly favorable course. There is usually a history of many years of respiration of dust in the patient's occupation. Cases in which there is no accompanying tuberculosis must be distinguished from those in which an occasional dust effect is added to an already existing tuberculous process.

Glycosuria in Vagrants.—Hoppe-Seyler has remarked the frequency with which glycosuria occurs in those who have led an irregular, wandering life, being poorly nourished and having undergone hardship. Five instances are recorded. They are not true cases of alimentary glycosuria, but passing disturbances in the carbohydrate metabolism, together with disturbances of circulation, interstitial and parenchymatous diseases of the liver and pancreas, play a rôle.

Late Diphtheria in the Nasal Pharynx.—Eschweiler relates a case, and believes the condition more frequent than literature indicates. Many instances of supposed primary rhinitis fibrinosa diphtheritica do not begin in the nose but in the nasal pharynx. In chronic cases the naso-pharynx must be carefully cleansed by the physician, and after a cure is effected any adenoid growths present must be removed to prevent recurrence.

Upon the Causes of Hypertrophy of the Heart in Kidney Diseases.—August Bier believes that hypertrophy of the heart and the changes in the blood-vessels which accompany it are purely compensatory effects without which prolonged existence would not be possible. This position he goes on to justify and explain by physiological and physical conditions and facts, and to show that the changes are useful and necessary to the economy.

Mucous Colic and Membranous Catarrh of the Large Intestines.—R. Schütz states that authors do not agree upon questions of etiology in colica mucosa and enteritis membranacea, and he presents four instances, all in women, by which he hopes to throw some light on the distinctions to be made between them.

Case Reports of Tendon Rupture.—Oscar Vulpius gives notes of a number of cases observed in which the extension apparatus of the forearm or other muscles were involved, and quotes the literature of rupture of the quadriceps tendon.

Muscle and Tendon Laceration of the Biceps Brachialis.—Ernst Pagenstecher reports upon two new cases, and refers to his previous article in the *Berliner klinische Wochenschrift*, No. 16, 1895.

Deutsche med. Wochenschrift, April 12 and 19, 1900.

Epidermolysis Bullosa Hereditaria.—Otto Michaelsen reports the case of a young woman seventeen years old, who presented herself for the treatment of blisters appearing on the hands and feet, accompanied with great pain and profuse sweating. She was of healthy appearance, and the internal organs were found on examination to be normal. The palms of the hands were wet with perspiration and were covered with numerous blisters, the size of a pinhead to that of a walnut. Some had collapsed, their integumentary covering lying in fine creases on the base. There was no scar formation on the skin, and the nails were normal. On the soles of the feet, and especially between the toes, there were many excoriations due to the maceration of the integument, and there were also numbers of blisters of various sizes, like those on the hands, which were very tender on pressure. The patient had suffered from this trouble since her earliest childhood, the bullous formation appearing first on the feet and later (about the twelfth or thirteenth year) on the hands. The affection was always worse in warm weather and was intensified by hard work, especially harvesting. There were no lesions either preceding or accompanying the blisters which suggested in any way an urticaria. An inquiry concerning the girl's antecedents revealed the fact that she had inherited the disease from her father and he from his mother. In all twelve persons, four males and eight females, in this family suffered from epidermolysis. There were four generations of sufferers, the patient under observation being in the third, the children of her sister constituting the fourth.

Ovarian Cyst Impeding Labor Removed by Posterior Colpotomy.—A. Hesselbach reports the case of a woman thirty-one years old, who had had five normal pregnancies. During the latter half of the sixth she suffered severely from sacral pains. Labor began but progressed slowly, and examination revealed a cystic tumor between the rectum and vagina, projecting into the latter in horseshoe shape partially encircling the child's head. As the tumor offered an absolute obstruction to delivery, and craniotomy was out of the question, removal of the cyst was the only alternative. The vagina was incised and the tumor dissected out with the finger, and finally the entire hand was introduced. It was impossible to replace the cyst, so it was evacuated through a slight puncture and the sac was drawn as far as possible into the vagina. Delivery was then effected by means of the forceps, the vagina was rapidly cleansed as well as it could be, and the sac was pulled down so as to bring the pedicle within reach. This was ligatured and incised. The child was slightly asphyxiated, but was easily resuscitated. The woman made a good recovery.

Mobility of the Heart in Change of Position of the Body.—Determann finds that in general the heart moves 2½ cm. to the left and 1 cm. upward when a healthy person lies on the left side, and moves about 1½ cm. to the right and ½ cm. upward when he lies on the right side. In some cases, however, the organ may be displaced 6½ cm. to the left or 4 cm. to the right without causing any distressing symptoms. The greatest change of position of the heart in varying positions of the body occurs in the emaciated, those who lead a sedentary life and whose muscles are flabby. In many persons who cannot lie on one or the other side because of palpitation, pain, and other distressing symptoms, this increased mobility of the heart exists. Occasionally the symptoms are even more severe—a rapid and irregular pulse, marked oppression, etc. The treatment of this condition consists, first, in improving the general health by means of a generous diet, arsenic, iron, hydrotherapy, etc. The abnormal sensitiveness of the heart, of which many of these patients complain, may be relieved somewhat by the bromides.

The Indication for a Mastoid Operation.—Richard Müller says that every case of acute middle-ear suppuration which, in spite of proper treatment, continues for two weeks in undiminished intensity without showing any tendency to improvement, must be treated by opening of the mastoid antrum, even when there are no threatening symptoms present. This, he says, is not to be taken too literally and absolutely, for while it is a rule which one may always follow with safety, yet in certain cases one might be justified in delaying operation a little beyond the limit mentioned.

Unusual Displacement in Fracture of the Leg.—Reichenbach reports a case of fracture of the leg in which the upper fragment of the tibia was displaced to the inner side of the lower and in the same frontal plane, the upper portion of the fibula being in front of the lower and in the same sagittal plane.

Archives of Pediatrics, May, 1900.

Tuberculosis of the Female Genital Tract in Children.—Martha Wollstein reports the case of a little girl aged two years, who died on Randall's Island. At the autopsy there was found marked purulent bronchitis of both lungs, and discrete miliary tubercles were scattered throughout the substance of all the lobes. The peritoneal surface of the rectum was covered with exudate and studded with tubercles. The left ovary was normal, but the right ovary was covered with a layer of cheesy material extending into the cortical layer, where there were many miliary tubercles which had undergone cheesy degeneration and did not involve the medulla. The mucous membrane of both Fallopian tubes was converted into a cheesy mass. There were two abscesses, one in the right broad ligament and one in the cul-de-sac of Douglas. No clinical history of the case could be obtained.

The Ambulatory and Hospital Management of the Gastro-Intestinal Derangements of Infancy in the Summer Months among the Poor of Large Cities.—Henry Koplik emphasizes the fact that the gastro-intestinal diseases, both mild and severe, are in the vast number of cases infectious, and urges scientific examination of infants' diarrhœal movements before treatment is inaugurated. Treatment is not so laborious in the simple diarrhœa of the coli variety as in the severer forms of streptococcal infection. The ambulatory method of treatment (dispensaries and out-door services) of summer diarrhœa is far more satisfactory than the hospital or sanitarium method. The author gives a long list of reasons why this is the case. A camp or colony of huts in the country, with arrangements for plenty of air and light, would be an ideal hospital for the treatment of sick infants.

The Care of Premature Babies in Incubators.—James D. Voorhees gives the results of the use of the incubator in the Sloane Maternity in two years' time, one hundred and six babies having been treated. Twenty-nine died within four days, all but three of these being more or less asphyxiated at birth. Seventy-seven survived the first four days. Of these thirteen died in the hospital. The condition of three was poor at the time of discharge, fair in twenty-four, and very good in thirty-seven; thirty-two were above their birth weights and fifty-seven were gaining in weight. Three months later, thirteen were reported as having died, twenty-eight were unheard from, and twenty-one were found to be alive and doing well. The author gives full description of incubators and methods of treatment.

The Application of a Rational Surgical Technique to the Removal of the Foreskin.—By Leonard Woolsey Bacon, Jr.

Occasional Periscope of Teratology.—By J. W. Ballantyne.

Archiv für Derm. und Syph., vol. i., Nos. 2 and 3, 1900.

The Favorable Effects of X-Rays in Lupus.—Himmel makes a study of the results of Roentgen-ray medication in lupus and the side effects upon intact skin and appendages. He finds that the relatively harmless inflammatory reaction produced upon the skin by the action of the rays, as soon as the latter have penetrated to the subcutaneous cellular tissue, acts favorably upon the lupus infiltration and destroys the bacilli and brings about healing of the skin. The *x*-rays are, therefore, of benefit, but naturally do not prevent new bacilli from lodging here and producing new nodules.

Endothelioma of the Skin.—Eduard Spiegler presents with several portraits and microscopic drawings a review of the literature of endotheliomas of the skin or rare forms of skin tumor. The case represented by a colored lithograph is a striking one from the great number of tumors present and their peculiarity of formation. Histologically, they resemble sarcoma at times and become malignant in course, though usually they appear to be clinically innocent.

A Method of Rapid Staining of the Gonococcus.—Uhma gives a way of rapidly coloring Neisser's diplococci in fresh unfixed preparations. The object-glass is moistened with a one-half to one-per-cent. neutral red solution (Grübler) and dried. A small drop of pus is placed on a cover-glass and laid upon the previously prepared object-glass, pressed down, and examined. The gonococci are the first morphotic elements to appear colored.

The Treatment of Some Instances of Blennorrhœa of the Eyes with Largin.—Almkvist gives a brief account of this newer method of treatment, in which he employs a two-per-cent. solution of largin.

Much seems to depend upon early diagnosis and prompt beginning of treatment, just as is the case with silver solutions. When the cornea is not yet implicated, the results are favorable.

Epidermolysis Bullosa.—Rona describes two new instances, presenting as after-effects atrophy of the skin, cysts of the epidermis, and trophic lesions of the nails. As to the identity of this form with the hereditary form described by Goldscheider, the writer is not at present willing to commit himself.

Bulletin de l'Académie de Médecine, April 17, 1900.

Post-Mortem Diagnosis of Canine Hydrophobia.—M. Nocard instituted a series of investigations in order to ascertain whether the lesions of the plexiform ganglia of the pneumogastric were always present in rabies, as stated by Van Gehuchten and Nelis. The first dog had rabies after seventeen days of incubation, and was killed seventeen hours after the first appearance of the symptoms. The cells of the ganglia were absolutely unaltered. The same results were found in the case of a second dog, killed in the first attack after twenty-three days of incubation. The third dog, seized with madness after thirty-two days of incubation, had marked lesions of the ganglia. Half the cells were destroyed, and the whole of each ganglion was infiltrated with leucocytes. A fourth dog had very slight lesions. On the whole, the author thinks that when the results are negative the dog cannot be considered to have been free from suspicion of rabies, and the persons bitten should be taken to the Pasteur Institute.

Goat Vaccine among the Kabyles.—M. Hervieux reports the results of Fargin's experiments with this vaccine in a country where bovine vaccine is most difficult to obtain. The result was in every respect equal to that obtained by cowpox, and the author recommends its use in that country, where cows are so rare that in seven months' time Fargin never saw one, and never had beef to eat.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The Progress of the War.—Since I last wrote Lord Roberts has carried out some careful movements for clearing the Boers from the southeastern part of the Orange Free State. When this district is quiet, he will be able to make a forward movement with much less risk to his communications. But everything proves that Roberts is not going to be in a hurry. He is quite aware that a quick end to the war has been expected of him, but he is equally aware that if he gets into "an entanglement" (as the British euphemism goes), there is no one to relieve him. Therefore, he intends to be perfectly sure that his force is properly equipped, adequately mounted, suitably clothed, attended by all necessary medical men, and provided with an unfailing supply of good food before he starts. Humanity and prudence alike dictate his proceedings, and I confess that I am a little astonished to find otherwise clear-headed critics of the campaign holding him to be dilatory. A little medical knowledge would have saved them from rash judgments. Besides Roberts' manœuvres between Bloemfontein and the Basuto frontier, though primarily undertaken to preserve his railway communication with Cape Town, may at any moment become actively offensive and even decisively successful against the Boers; for while the British cavalry drive them from Dewetsdorp and Wepener northward, it may be possible for another force to cut off their retreat at Ladybrand. In the course of the next few days it will be decided whether the Boer forces still left south of Bloemfontein are surrounded and made to surrender, or prove able to escape and re-form between the English and Pretoria. There are many loopholes in Roberts' projected circle, and with their great mobility and perfect knowledge of this country I shall not be surprised if the Boers burst through it; but I do not believe that either event will have any rapid impression on the progress of the war. For, whatever happens, the road to Pretoria will be strongly held, and Roberts will be resisted all along the line. The medical officers of the British army, under whose care many Boer sick and wounded prisoners have now passed, all state that the spirit of the Boers is quite unbroken, and that obstinate fighting must be expected of them to the end; and what the patient while he is really ill tells the medical attendant is apt to be true.

Sir William MacCormac and Mr. Treves have, I learn, both arrived back in England. During their four months' service with the army they rendered excellent help to the Royal Army Medical Corps, their moral support being as valuable as their scientific aid.

The Imperial Yeomanry Hospital.—The staff of this hospital, which arrived in Cape Town early in March, have been ordered to Deelfontein, which Lord Roberts has selected as the first site of the hospital. This place, which is not marked on many maps, is about four hundred miles from Cape Town and thirty miles south of De Aar Junction. There is no town, the only buildings being the railway station, the general store, and a pumping-house with machinery capable of raising a practically unlimited amount of pure water from a deep well. As De Aar Junction is the place where the railway lines to Bloemfontein and Kimberley diverge, it would seem that from every point of view the spot chosen for the Imperial Yeomanry Hospital is a good one. However extended Lord Roberts' front may be, the hospital will be directly behind it; it also will be a convenient stopping-place for any sick and wounded following either upon Lord Methuen's operations on the Vaal River or upon the long-expected relief of Mafeking; being two days' train inland, the sufferers will be saved much of the weary railway journey which has been so trying to the patients brought down to the base hospitals at Wynberg; and lastly, Deelfontein is a pleasant and healthy place with the splendid water supply to which I have referred. It should be added that the place now possesses a newspaper, for Mr. Newland-Pedley, the dental surgeon to the Imperial Yeomanry, has started a journal which is called *The Devil's Fountain.*

The Effect of Typhoid Fever and Privation in Ladysmith.—In Ladysmith, as was said in these columns early in the investment of the town, none of the factors were absent that should make for the development and spread of enteric fever. The report of the army medical department of Great Britain for 1898, which has only just been given to the public, but which presumably fell under official eyes at least a year ago, mentions the place as one where enteric fever is constantly prevalent—a fact which makes its selection as a base for military operations appear rather unfortunate in medical eyes. Add to this endemicity the circumstances of a protracted siege, and you get a position in which it was safe to prophesy that the worst scourge of armies would be severely felt. And now we know the figures. The siege commenced on November 2, 1899, when the effective strength of the garrison was 572 officers and 12,924 men. The effective strength at the end of the siege, that is, on March 1, 1900, was 403 officers and 9,761 men, the majority of whom were, however, only "effective" in name. When the town was relieved, 154 officers and 2,624 men were in hospital. The total admissions to hospital during the siege numbered over 10,000, and during the last six weeks the deaths numbered 8 per diem, chiefly from enteric fever. About 560 persons (officers, men, and followers all told) died of disease during the siege, the number of wounded being almost the same. But of the wounded only 8 officers and 51 men died; while 18 officers and 193 men were killed outright in action. From these figures it will be seen that enteric fever was the worst foe encountered by the Ladysmith garrison.

The American Hospital Ship, the *Maine*, arrived in England on April 23d, taking with her one hundred and fifty-one men and twenty-one officers. Nearly all the patients were convalescent by the time the ship reached Southampton, and Lady Randolph Churchill was able to announce an excellent voyage with favorable weather all the way.

Severe enteric fever has broken out in Kimberley.

Dr. Scholtz, a well-known physician in Cape Town, has been appointed physician to the Langman Hospital. This, the second largest of the hospitals supported in South Africa by private enterprise, is stationed at Bloemfontein.

Assistant-Surgeon Jackson, a prisoner in Pretoria, has died there from dysentery. There are, by the way, some ominous stories current in Lord Roberts' army concerning the medical and sanitary care that is received by the numerous British prisoners in Pretoria. These can be but stories, for no one has come through from Pretoria for many weeks now. A few released prisoners, and Mr. Winston Churchill, and one or two officers who escaped have narrated their experience and describe the treatment received by the prisoners, as it came under their personal knowledge, to be on the whole good. Feeding is rough, and the price to be paid for even the smallest luxury is very high, but there is not, unless there has been some sudden deterioration in the Boers' humanity, the entire absence of civilized treatment that has been described in lurid terms by one or two correspondents for the British press. The Boer prisoners in British hands have suffered severely from enteric fever. Doubtless it is rumored in Pretoria that the British are treating their prisoners shamefully, while, as a matter of fact, these prisoners have received the most careful attention.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MIDWIVES CONTROVERSY—SURGERY OF THE STOMACH—QUESTIONS CONCERNING CANCER—LATE RICKETS—THE QUEEN IN IRELAND—THE ROYAL ARMY MEDICAL CORPS—SIR BATTY TUKE CANDIDATE FOR PARLIAMENT—LIVERPOOL TROPICAL SCHOOL—DEATHS OF WALTER CLEGG AND R. G. PATTESON.

London, April 20, 1900.

THE midwives bill is rousing a good deal of opposition. It would have been more effectual if it had been manifested earlier, but the profession seemed apathetic and the corporations were hoodwinked. In the report stage the supporters threw off the mask and showed that they were determined to license midwives and to decline all restrictions. Some, indeed, affected to keep up the delusion that the midwives when registered would not be independent practitioners, and were willing for them to be required to send for a doctor in dangerous cases. But they refused to penalize not doing so. This has opened the eyes of some, and the opponents are being encouraged.

A committee has been formed to oppose the bill, and more meetings have been held or arranged for. An attempt is being made to show members of Parliament the dangers threatened to the public. Dr. Rentoul is again to the fore with a plan to form an association of ten thousand members. He formulates eight objections, and I am afraid that his effort will not be sufficiently concentrated to defeat the bill.

Dr. Glover is being called over the coals by one party for his action in this matter. As I told you, he was challenged to resign from the General Medical Council and offer himself for re-election. He has replied to this that he is not a mere delegate. It is natural that he will not accept the mandate of any committee opposed to the views he expressed openly when a candidate. It is obvious, however, that he is losing touch with many electors on this subject, the more so as events show the objects of the promoters in their nakedness. I am sorry, because he is an excellent representative and has done good work. It is said that he is a general practitioner, but then it is only as a very high-class general practitioner that he can be spoken of—quite on a level with the higher grades. He lives in the most aristocratic part of Islington, has been honorary surgeon to the dispensary, and enjoys the confidence of a large, high-class clientèle. It may well be, therefore, that he looks upon midwifery with a very different eye from that of the struggling general practitioner in a poor neighborhood.

If the present bill passes, a doctor may be expected to be at the call of an ignorant midwife; but if he keeps an unqualified assistant who has been recognized for years as capable, he is liable to be removed from the register. If these ignorant midwives are to be registered, we may look for a great increase in quackery of all kinds and of abortion-mongering. Years ago a member of Parliament urged upon me this last danger. We have seen enough of it without registration.

A curious circumstance has occurred in connection with this bill. The Dublin College of Physicians issued a circular letter, asking the Irish members of Parliament to endeavor to get the measure extended to Ireland. Now the Irish Medical Association has issued an urgent appeal to the members of Parliament to oppose such extension, and goes on to say that the existing provision in Ireland is as nearly perfect as possible. It appears that the college acted under the misapprehension that the bill would prevent the midwives of the Rotunda and Coombe Hospital from practising in England. This is not the case. But the bill would register a host of untrained women, who could flood Ireland and compete with her trained midwives.

Any one who had not followed the progress of surgery on the stomach might well have been startled when it was announced that Schlatter had performed a resection of the complete organ, and that the patient lived in comparative comfort for fourteen months. Seven other complete gastrectomies have since been performed, of which three of the patients lived for thirty-six hours, six weeks, and several weeks respectively. Thus of the eight cases the mortality is four, or fifty per cent. Of almost complete gastrectomies, in which at least three-quarters of the organ was removed, fourteen cases have been reported, according to Mr. Mayo Robson, who stated in his Hunterian lectures at the Royal College of Surgeons that ten of the patients had recovered, giving a mortality of 28.5 per cent. Of course the survival may be of very varying periods in different cases, but in these lectures Mr. Robson could not give full details, as he had to go over the whole field of the surgery of the stomach, which he did with great effect. He looks hopefully on the future of gastric surgery, and appeals to physicians with the usual surgeon's cry for earlier diagnosis, so that operations if necessary may be performed before the patient's recuperative powers are exhausted. In perforating ulcer this necessity has been pretty well brought home to physicians, but there are many other cases in which a consultation with a surgeon might well be urged, and of course the earlier the better. The cases in which surgery has made advances were thoroughly discussed by the Hunterian lecturer, who was able to say that his last thirty-two operations on the stomach in private practice had all resulted in recovery.

Sir W. M. Banks has given new life to several questions connected with cancer by the views he expressed in his recent Lettsomian lectures. One of these is the relation of diet to cancer, and though this in some form is a very old question, we have really hardly any definite knowledge on the subject. The impression of Sir W. M. Banks is that overfeeding predisposes to the disease, especially excess of flesh food. Here we touch another undecided question—the alleged increase of cancer. Sir W. M. Banks believes that there is a real increase; therefore, accepting this as a fact, he appeals to it as supporting the view that excess of meat food conduces to the development of the disease. No one doubts that there has been a progressive increase in the consumption of meat for some twenty or thirty years, and that increase has been most marked among the laboring class. This, however, is a long way off from proof of the hypothesis. Admitting the concurrent increase of two circumstances by no means proves a relation between them; and considering the connection of gout with flesh diet, the suggestion that cancer occupies a similar position is being warmly disputed and in some quarters pooh-poohed.

Amony other explanations of the increase of cancer —when such increase is admitted—may be named more careful diagnosis, more accurate statistics and nomenclature, and increased longevity. Cancer, being a disease of the later period of life, might be expected to increase with the prolongation of that period. But whether the two have increased *pari passu* is naturally more difficult to show than that there has been an absolute increase in one.

The question of parasitism was treated by Sir W. M. Banks with a certain degree of reservation, but he freely admitted that the bodies described as parasites by various observers are special organisms. Whence they come, what they do, is another point. He is convinced they exist, and gave some experiments by Mr. Montsarrat, of the Liverpool Infirmary, confirmatory of those of other bacteriologists. It is to these specialists we must look to settle the question. The question of treatment derives much importance from the successes that have been achieved of late by extensive operations. Sir W. M. Banks was a pioneer of this practice, but has never gone to the extremes of some. His practice has been much the same as that of Samuel Gross. Indeed, it is to these two surgeons that the modern operative treatment ought to be dated, for they carried it out faithfully when not a few actively opposed them. Now it is rather sad to see surgeons attributing the origin of the practice they once opposed, but now adopt, to the labors of later Germans, rather than to the British and American operators, Banks and Gross, who initiated the method.

Among the cases exhibited at the Medical Society was one of late rickets, shown by Mr. Muirhead Little. His patient was a girl aged seventeen years, who was in good health up to the age of five, at which time knock-knee was noticed. At seven years she took to crutches. She was said to have broken both thigh bones, one six, the other five years ago. When seen by Mr. Little (October, 1899), her length in the recumbent position was forty-four inches. The head and ribs showed signs of rickets; the lower end of the radii and the ulnæ were much enlarged; the shafts of the femora curved forward and outward, making progression cross-legged; the tibiæ were normal. Macewen's operation was performed on one knee, when the bone, instead of being hard, was so soft that a mallet was scarcely necessary. The bones were unusually pervious to x-rays. Only half the normal amount of calcium was present in the urine. The marked enlargement of the epiphyses distinguished this and similar cases mentioned from rachitis adolescentium.

Mr. Kellock thought it might be a case of late rickets, but there were points named which suggested to him mollities ossium or fragilitas ossium, or perhaps a combination of them.

The president (Dr. F. T. Roberts) said the case strongly resembled rickets, and the bone ends were certainly enlarged. The changes in the chest were not those of early rickets, but this was not usually the case in late rickets.

Mr. Little replied that the idea of rickets only affecting the epiphyses was novel; the whole bone was involved; fracture was frequent, but was of the greenstick kind in rickets. This patient had never suffered any pain. He used the term "late rickets," as it resembled cases so described more than any others.

The Irish royal colleges were naturally among the institutions to present loyal addresses to the Queen on the occasion of her majesty's happy visit. The City of Dublin Hospital is henceforth to be distinguished by the prefix Royal.

The Royal Army Medical Corps continues to gather fresh laurels at the war. This is the more significant just now when reputations are being lost in other directions. Mr. Treves has returned home, and Sir W. MacCormac is on his way. They have had a pleasant trip at the country's expense, and the army surgeons received them as brethren.

Sir Batty Tuke is a candidate for the representation of the universities of St. Andrews and Edinburgh, vacant through the death of Sir William Priestley.

An anonymous benefactor has endowed a colonial fellowship of £100 a year for five years in the Liverpool School of Tropical Medicine.

Mr. Walter Clegg, M.R.C.S., died on Monday, aged seventy-nine years. For nearly forty years he was the coroner for the Boston division of Lincolnshire. He was the son of a Wesleyan minister, and founded *The Boston Guardian* in 1854. He served in the Crimea as surgeon to the Second Battalion Rifle Brigade. While there he acted as war correspondent for *The Illustrated London News*. He was one of the oldest war correspondents, having begun that work nearly as soon as Sir W. H. Russell, and he lived to be one of the oldest coroners. He was mayor of Boston in 1868 and 1869. Subsequently he was medical officer of health up to about three years ago.

The death is announced of Dr. R. G. Patteson, surgeon to the Meath Hospital, Dublin. Though hardly forty years old, he had achieved a high position. He graduated in arts and medicine at Trinity College in 1885, and took the travelling prize of Dublin University in 1886. After studying in London, Vienna, and Berlin, he returned to Dublin, took the fellowship of the College of Surgeons, became one of the examiners, and carried on his work until ill health, which had troubled him for long, compelled him to withdraw from his arduous labors. He made many contributions to surgical and biological literature.

Tetanus.—Inject fifteen minims of a two-per-cent. carbolic-acid solution every two hours.—*Il Policlinico.*

DISINFECTION OF THE UMBILICUS IN ABDOMINAL OPERATIONS.

To the Editor of the Medical Record.

Sir: Perhaps the following will be of some interest to the readers of the Medical Record: In the preparation for abdominal operations, especially that of disinfecting the abdominal walls, there is a detail which in this country is not perhaps very widely known, but does deserve a wider acquaintance; it is the complete cleansing and disinfection of the umbilicus, made possible by traction upon it with a clamp forceps. This smoothes out the numerous depressions naturally situated there, and offers an uninterrupted and smooth surface for thorough cleansing and disinfecting.

The above is from observation in the Paris hospitals, in which it is part of the preparatory technique.

James Taylor Hanan, M.D.

Brooklyn, N. Y.

"HOW TO SEND ANATOMICAL SPECIMENS BY MAIL."

To the Editor of the Medical Record.

Sir: An article appeared in the issue of April 21st, p. 696, by Steward Gordon, on "How to Send Anatomical Specimens by Mail." I wish to mention one class of specimens to which I have found practically similar methods not applicable; namely, soft specimens like the intestinal mucosa. The pressure of the lint fibre in specimens I have seen caused a net-like indentation which rendered them almost valueless for museum purposes; and the distortion, histologically, unless understood, causes confusion, and in some cases might lead to seriously incorrect statements. Specimens of this kind are preferably sent in fluids; and screw cases are made especially for sending them by mail.

D. S. Lamb, M.D.

Army Medical Museum, Washington, D. C.

WHAT IS THE BEST POSTURE FOR THE PATIENT IN BED AFTER ABDOMINAL SECTION, PARTICULARLY IN PUS CASES?

To the Editor of the Medical Record.

Sir: I was much interested in the article by Dr. George R. Fowler, entitled "Diffuse Septic Peritonitis, with Special Reference to a New Method of Treatment, namely, the Elevated Head and Trunk Posture, to Facilitate Drainage into the Pelvis, with a Report of Nine Consecutive Cases of Recovery," and published in the Medical Record of April 14, 1900.

During the past ten years, in the after-treatment of nearly all my abdominal sections—particularly pus cases—and much for the same reasons given by Dr. Fowler, I have employed the method advocated by him, and have not been persuaded to change it. The head and shoulders of my patient are elevated upon several pillows, the castors in the lower posts of the bedstead are removed, and a round hair pillow is placed under the knees of the patient, for the double purpose of preventing slipping down in bed and securing additional relaxation of the abdominal muscles; this relaxation affording comfort to the patient and favoring peristalsis and the descent of fluids toward the pelvic cavity.

In the after-management of these cases it is both curious and instructive to note the different theories upon which we act—a sort of theoretical mental gymnastics of kaleidoscopic change of tint and figure. Only recently, it has been enjoined upon us that better results will follow the employment of a posture exactly the reverse of that advocated by Dr. Fowler; that is, to elevate the hips of the patient in order to favor the diffusion of fluids over an extensive area of peritoneal surface, which somehow digested the contained poisons, or even absorbed them with greater facility. To cite a common phrase: "A larger area of peritoneal surface can take care of a phenomenal amount of toxins."

Mirabile dictu! Dr. Fowler prefers, without previous irrigation, to wipe the abdominal cavity dry with gauze, leaving in no decinormal salt solution to attenuate the toxins; rehabilitates glass drainage—sometimes employing several tubes, reinforced by numerous wicks or strips of gauze, and then delights in observing a copious exit of fluids into the superimposed dressings. Adding preliminary irrigation, Lawson Tait also, throughout his brilliant and successful career, laid the greatest stress upon an endeavor to keep the peritoneal cavity free of all accumulating fluids; hence his constant reliance upon the drainage tube in all pus cases or when bleeding was feared from ruptured adhesions. He would keep the peritoneal membrane as dry as possible; so would Dr. Fowler. Each may have had a different theory upon which to base the practice, but the latter virtually is identical with both operators. In the practice of our art, truly "the heresy of to-day is the creed of the next."

Dr. Fowler is to be congratulated upon his enviable record in an ordinarily hopeless class of cases, and his results speak volumes for the treatment employed, although it cannot justly be claimed that this treatment is a distinctly new method.

Henry K. Leake, M.D.

Dallas, Tex.

Reviews and Notices.

Transactions of the British Orthopædic Society. Volume III. Published by the Society. Bristol: J. W. Arrowsmith. 1899.

Eighty-nine bound pages, giving reports of various sessions for 1897–98, of especial interest to the orthopædic surgeon.

Diseases of Women. A Text-Book. By Charles B. Penrose, M.D., Ph.D., Professor of Gynæcology in the University of Pennsylvania, etc. Illustrated. Third edition. Philadelphia: W. B. Saunders. 1900.

A few additions have been made in this new issue, but the author has carefully revised the text. A feature of the work is that in most instances but one method of treatment is given for each disease, thus rendering the student's chances of confusion less. Many problems are made much clearer by the illustrations given. The work seems to be justly popular.

Refraction and How to Refract: Including Sections on Optics, Retinoscopy, the Fitting of Spectacles and Eyeglasses, etc. By James Thorington, A.M., M.D., Adjunct Professor of Ophthalmology in the Philadelphia Polyclinic and College for Graduates in Medicine; Assistant Surgeon at Wills' Eye Hospital, etc. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

Those who have read the author's little manual of retinoscopy with the plane mirror will not be surprised to find here a complete but succinct guide to the determination and correction of ametropia, beginning with a consideration of rays of light and of elementary optical principles. Successive chapters deal in a thoroughly practical manner with the standard eye, the various errors of refraction, the balance of the external eye muscles, cycloplegics, and, finally, with the application of various methods to the prescription and fitting of correcting glasses. The book can be recommended not only to beginners in the study of ophthalmology, but to those practitioners and students as well, whose limited knowledge of mathematics precludes the study of Helmholtz or Donders. A purist might take exception to the author's use of the word "refract," in the sense of testing refraction—a barbarism which is not excused by its prevalence. Usage, so called, is as unreliable a guide in the choice as it is in the accentuation and pronunciation of words, to judge by the coining of such terms as "refractionist" and "refracting opticist." As the author himself says, refraction has come to mean the optic condition of an eye in a state of repose or under the physiological effect of a cycloplegic. Let us use it in this sense, then, and when we wish to speak of determining ametropia, let us use two simple words instead of a single one which, in its misapplication, has a meaning "by courtesy of complicity" only.

Essentials of Medical Chemistry, Organic and Inorganic, containing Questions on Medical Physics, Chemical Philosophy, Analytical Processes, Toxicology, etc. Prepared especially for students of medicine. By Lawrence Wolff, M.D., Demonstrator of Chemistry, Jefferson Medical College; Physician to the German Hospital of Philadelphia; Member of the German Chemical Society, of the Philadelphia College of Pharmacy, etc. Fifth edition, thoroughly revised by Smith Ely Jelliffe, M.D., Ph.D., Professor of Pharmacognosy, College of Pharmacy of the City of New York; Clinical Assistant, Department of Neurology, Columbia University, New York. Philadelphia: W. B. Saunders. 1899.

The chapters dealing with organic chemistry have been considerably modified and enlarged, more particularly in the discussion of physiological chemistry. An attempt has been made to present a brief outline of the present status of our knowledge of the chemical constituents of the human body. The revision by Dr. Jelliffe brings the subject-matter well up to date.

A Treatise on Surgery, by American Authors. Edited by Roswell Park, A.M., M.D. Condensed edition. 8vo, 1,262 pages. New York and Philadelphia: Lea Brothers & Co. 1899.

This condensed edition of the larger work is the result of a wise conclusion to meet the growing requirements of the busy practitioner, whose time and opportunities for the consultation and study of elaborate treatises are necessarily limited. From the standpoint of condensation, which is the main one to consider under present circumstances, the work is a conspicuous success, giving all that is required under the respective sections and conscientiously preserving all that is of practical value. The general arrangement of the elaborate work is well preserved, and in many respects fully answers all its essential purposes. On behalf of the editor and his able collaborators, it is but just to say that the work is fully up to the times, not only from a pathological but an operative point of view. In respect to the bacteriology of surgery proper, substantial progress has been made in adapting the resources of the laboratory to the requirements of advanced study of the blood constituents, tumor elements, classification of growths, and possible microbic origin of malignant processes. It represents a very large amount of valuable research in a very small compass.

La Pratique des Accouchements Obstétrique Journalière. Par Henri Variner, Professeur Agrégé à la Faculté de Paris, Accoucheur des Hôpitaux, Secrétaire Général de la Société d'Obstétrique, de Gynécologie et de Pædiatrie. Avec 387 figures. 437 pages. Paris: G. Steinheil, Éditeur. 1900.

This valuable work, founded upon the author's lectures, aims at the instruction of the student by means of illustrations reproduced from actual photographs. While prominence is given to these, the text is none the less full and clear. Chapter I., on the diagnosis and hygiene of pregnancy, is especially useful to the student; in fact we do not recall any more lucid description of the details of obstetric palpation. The section on diagnosis is most practical. Chapter II., which deals with normal labor, including a hundred and thirty pages, is profusely illustrated. Chapter III. deals with delivery, and discusses at length the placenta and its mode of expulsion. Numerous photographs, taken at the bedside, are introduced as in the previous chapter. American readers will disapprove strongly of the advice to make traction on the cord. Chapter IV., on the normal puerperium, treats thoroughly of the subject of involution, especial attention being paid to the changes in the uterine tissues. Numerous original drawings are introduced. The last hundred pages are devoted to a review of the subject of puerperal sepsis, particularly the prophylaxis. Several sections are given to bacteriology. In general it may be stated that this monograph is most praiseworthy. The author's style is original and pleasing; the illustrations are numerous and, though not always satisfactory from an artistic standpoint, they are well calculated to catch the eye of the student and to impress upon him the points made in the text. The paper, type, and general make-up of the book are above the average.

Mentally-Deficient Children: their Treatment and Training. By G. E. Shuttleworth, Baltimore, Md. Second edition. Illustrated. Philadelphia: P. Blakiston's Sons & Co.

In this new edition there is contained additional matter bearing upon education, and special measures recommended and adopted by school authorities, notably by the school board for London. The author's experience seems to qualify him well for a task which has been acceptably filled.

A Manual of the Diagnosis and Treatment of the Diseases of the Eye. By Edward Jackson, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic; formerly Chairman of Section on Ophthalmology of the American Medical Association; Member of the American Ophthalmological Society; Fellow and ex-President of the American Academy of Medicine. With 178 illustrations and two colored plates. Philadelphia: W. B. Saunders. 1900.

This volume contains six hundred and four pages. It is of convenient size, well printed on good paper, and so arranged that its contents are easily accessible. The author states in his preface that the "book is intended to meet the needs of the general practitioner of medicine and the beginner in opthalmology." It is truly an admirable work for this purpose, and contains much that will interest the advanced worker in ophthalmology. Written in a clear, concise manner, free from superfluous statements, it bears evidence of the author's comprehensive grasp of the subject. The text is divided into twenty chapters. One chapter is devoted to directions regarding "The Examination of the Patient, Case Records, etc.," one to "Remedies and their Applications," one to "Ocular Symptoms and Lesions connected with General Disease." The work is especially strong in the chapters which are devoted to the examination of the eye, the consideration of refraction and all that pertains to it, the disorders of muscles, and the ophthalmoscope. A valuable feature of the work is the short bibliography that follows each chapter, affording a means for the more comprehensive investigation of each subject. The term "multum in parvo" is an appropriate one to apply to this work. It will prove of value to all who are interested in this branch of medicine.

Clinical Department.

A CASE OF RAYNAUD'S DISEASE.

By F. J. BOWEN, M.D.,

MT. MORRIS, N. Y.

Mrs. G——, twenty-eight years of age, had for several winters suffered from symptoms corresponding to the description of the stage of local asphyxia of this affection. The fingers of both hands were affected, circulation apparently disappearing from about the distal and middle phalanges. Nutrition suffered in a corresponding degree. The parts affected appeared shrunken or withered and cold, the nails were dried and lustreless, and at one time she said that the tips of the fingers felt sore, as if almost to the point of ulceration. The patient would hardly be called anæmic, but was slender and might be spoken of as "thin-blooded." She was of nervous temperament. Her husband was a laundryman whom she sometimes assisted. When she came under my care in early winter, I advised her first, in regard to this work, not to go out of doors to hang up clothes; to wash with the hands in warm water for a moderate length of time was advised, but for a longer time was forbidden. In the way of medicine she was given tonics—compound syrup of hypophosphites I believe—and a preparation containing digitalis, nitroglycerin, and belladonna.

For the first time in several successive winters the symptoms were avoided.

A PIECE OF CHEWING-GUM IN THE URETHRA.

By W. H. PETERS, M.D.,

PROVIDENCE, R. I.

F. McG——, aged thirty-five years, consulted me for retention of urine, due to a foreign body in his urethra, which he said was chewing gum; that he inserted it in the meatus in March, 1899. He states that he has suffered the past ten months considerable pain in urinating, but not enough to cause him to seek medical advice. Lately his water has not been so free, and at the present time he has been unable to pass any water for eight hours. He gives a history of having had gonorrhœa ten or twelve times, but not since March, 1899. The bladder was very much distended, and the pain radiating to the glans penis was severe. There was a slight amount of blood about the meatus caused by his trying to dislodge the mass. At the bulb could be plainly felt a mass about an inch long, nodular, about half an inch or more at its greatest thickness, and hard to the touch. It was immovable. A very small-sized silver catheter was pushed by it with considerable difficulty; the water was drawn, and the patient was relieved. With a sharp uterine curette the body was broken up and found to be composed of chewing-gum, coated with phosphate of lime. The patient was given morphine gr. $\frac{1}{2}$, and sent to the hospital, where a few small pieces of a calcareous substance were removed by the visiting surgeon. The patient recovered without a chill. Dorr, in the *British Medical Journal* of May 14, 1892, reports a case in which a man had passed up his urethra a piece of chewing-gum, which in three months became largely coated with phosphates. It was removed by the supra-pubic method. As the gum was still soft and sticky it would have been impossible to disengage the jaws of the lithotrite or to crush the gum.

A CASE OF RAPID UNION IN FRACTURE OF THE THIGH.

By CLARENCE A. WELLS, M.D.,

QUINCY, ILL.

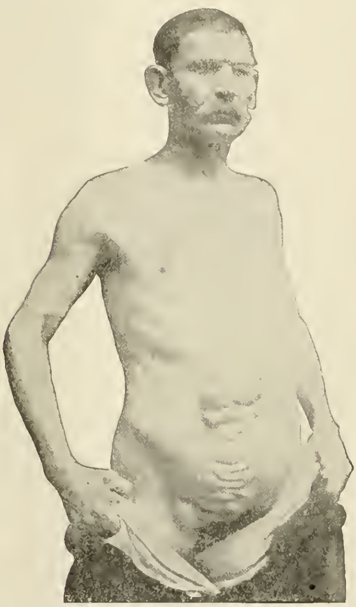
EGBERT H——, aged fifty-eight years, a male nurse in the hospital of the Illinois Soldiers and Sailors' Home, while going from the ward to the hospital kitchen, one hundred feet or more away, slipped and fell on the icy walk and sustained a simple, oblique fracture of the femur just below the trochanter. He suffered greatly from shock, so that the fracture was not dressed until the second day. All the signs and symptoms of that injury were present. Buck's extension was employed, and sand-bags weighing twenty pounds were applied tentatively. Counter-extension was secured by elevation of the foot of the bed. As the patient was restless, and as no fracture bed was used, the Hamilton long-side splint was omitted, and instead long sand-bags were used externally from the toes to the chest, and internally the entire length of the leg. Aside from some disturbance of the kidneys for a few days, the patient did well. The calls of nature were attended to in bed by means of the bed-pan. On January 20th, thirty-five days after the accident, the extension was taken off, because he complained so much of the discomfort. The fracture at that time was quite firmly united and the callus very marked. On January 24th the patient got up and used the wheel chair, and the next day began to walk with crutches. From that day to the present he has continued to walk around, and three weeks later even discarded the use of a cane. The injured leg is one inch shorter than its fellow.

AN ABDOMINAL VARIX.

By C. M. GALLOWAY, M.D.,

XENIA, OHIO.

T. G——, Co. A, Twentieth Regiment Ohio Volunteers, infantry, enlisted at Mansfield, Ohio, on October 22, 1862. He was discharged at Louisville, Ky., on July 15, 1865. The curious affection shown in the illustration began to make its appearance very shortly after his discharge from the service. It began at about the centre of the epigastric region as a small, tender swelling, and has gradually increased until it has assumed the proportions seen in the illustration. It cannot be reduced and is very tender on pressure. The mass over the stomach is somewhat larger in proportion to the other portion than the photograph indicates. It is almost as large as his clenched hand. On account of the movement of the abdomen in breathing it does not show very plainly. It is diagnosed at a varicose condition of the internal iliac vein. It seems to have no valves. No varicose veins are found elsewhere. It is supposed to have originated from pressure of his cartridge belt. It has not increased in size during the past few years.



Appendicitis.—Ice bag; opium by suppository; no food save a solution of peptone and sugared water. The bowels should be kept at rest for a week and then be gently washed out with a decinormal salt solution per rectum.—LAUBE.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FIFTH TRIENNIAL SESSION.

Held at Washington, D. C., May 1, 2, and 3, 1900.

(Continued from page 770.)

Second Day—Wednesday, May 2d.

THE second and final session of the Congress of American Physicians and Surgeons was held in the Lafayette Square Opera House in the afternoon. The meeting was called to order by the president, Dr. Bowditch, at 2:55 P.M.

The proposition made at yesterday afternoon's meeting for the appointment of a committee of three with full power to draw up and execute a memorial and petition to Congress of the United States, asking that charitable, religious, and educational institutions be relieved from such provisions of the war tax as are levied upon them and likewise upon legacies left to such institutions, was next taken up. The resolution was passed by unanimous vote, and the president appointed the committee as follows: Drs. F. C. Shattuck, A. Jacobi, and William H. Welch.

DR. KEEN, of Philadelphia, then offered the following resolutions of medical interest, which were unanimously carried:

"*Whereas*, The medical profession employs various kinds of exact measuring apparatus, particularly clinical thermometers, ureometers, lactometers, and volumetric apparatus; and

"*Whereas*, The physician should be able to obtain a written official guarantee of the accuracy of such apparatus; and

"*Whereas*, No bureau has been established by our government for this purpose, necessitating the importation of certain apparatus from countries possessing standardizing bureaus; therefore, be it

"*Resolved*, That the Congress of American Physicians and Surgeons heartily indorse the movement now on foot establishing such a standardizing bureau, where such work and other equally important may be undertaken.

"*Resolved, further*, That a copy of these resolutions be forwarded to the Secretary of the Treasury, to the president of the Senate, to the speaker of the House of Representatives, and to the chairman of the House committee on coinage, weights, and measures."

Sociological Status of the Physician.—Owing to the unavoidable absence of Professor Osler, whose announced subject was "Modern Therapeutics," DR. CLARENCE J. BLAKE, of Boston, spoke on the above subject. He said that the term "sociology," first used by August Comté less than sixty years ago, might be briefly and broadly defined as "the science of the laws of human relationship," and, as often happened in the presence of cognate intellectual processes working toward the same end, the suggestion of a concise definitive appellation furnished a rallying-point to which the various workers converged, and from which they went out strengthened by a sense of companionship and encouraged to more extended effort by a better comparative knowledge. Of all special educations that of the science and practice of medicine, when it was of the best quality, was the most exacting and made the largest demand upon the staying-power of the student; it was longer in duration, more confining, and required more intense application than the corresponding courses which led to a degree either in law or in divinity, and afforded a larger suggestive opportunity for collateral scientific reading. He believed that the hospital of to-day was something very much more than a repair shop; it was a school full of object lessons in the application of those qualities which are the "uprights," the "girders," and the "binding-rods" of the modern social structure; it was the most absolutely clean of all human habitations, and the present splendid successes of surgery in the amelioration of suffering and the preservation of life were due not only to the application of trained skill and intelligence, but to its operations under conditions of absolute sterilization which were microscopic in their minutiæ. He said that the entrance of women into hospital life and work was one of the sociological advances for which the medical profession was mainly responsible, a responsibility having a serious ethical, as well as an important economic side. The teacher had a regular stipend, allotted hours of work, and a definite holiday; the nurse, in private practice, had no regular stipend, no protracted leisure, and led an economically irregular life, with occasionally extraordinary demands upon her strength and powers of endurance. The medical profession, which had created the trained nurse to its own great advantage and with considerable extension of its helpfulness, was owed a debt which should be acknowledged not only individually but generally. The doctor spoke of the utility of medical inspection and of its necessity in many cases. He covered at some length the establishment and maintenance of charitable institutions, especially those suited for the mental development of the feebleminded and mutes. In closing, he said that another relationship which might be broadened beyond its individual phase was that between the doctor and the clergyman, and recent experiments based upon a proposition that the divinity student should have opportunities to see the practical side of hospital and other instituion work under medical guidance were so promising as to lead to the serious consideration of making this a definite part of the regular divinity-school instruction.

PRESIDENT BOWDITCH, at the conclusion of Dr. Blake's paper, stepped forward and said: "Now, gentlemen, it is my pleasant duty to ask your attention to our honored ex-president, who has cultivated the fields of medicine and literature with equal success, and who has kindly consented to express himself in his own charming verse on the evolution of the physician."

DR. S. WEIR MITCHELL then spoke, in part, as follows: "Mr. President and Fellow-members of the Congress: I will say a word in explanation of the unusual fact of my appearance here. It is perfectly well known, I venture, that never before in the history of medicine has a congress been addressed in verse. For this novelty you may thank the committee of the congress and my friend, its president."

Dr. Mitchell, upon rising to address the audience and upon the conclusion of the reading of the poem, was greeted with prolonged applause and was the recipient of many congratulations. He spoke with emphasis, feeling, and gesture. He described the doctor's honorable, dignified, and humanitarian station in life. The priests disagreed, but the doctor extended the universal hand of fellowship and good-will. The sentimental and pathetic introductions were delivered very impressively. One pretty verse reads:

"What sense of pleasure won that helping hand,
You best can tell, you best can understand;
Who, looking back across your busy years,
Know what your hands have spared of pain and tears."

His lines, "One bugle-note or one battle-call, one watch-word—*Duty*—that is all," was drowned in prolonged applause.

The congress was then adjourned until the evening, when the president addressed the assemblage upon "The Medical School of the Future." He said that among the intellectual movements that have characterized the century now drawing to a close, there was perhaps no one more deserving of careful study than that which was concerned with providing education for the people in the school, the academy, and the university. The importance of popular education became apparent in proportion as political freedom was secured for the people. Thus Viscount Sherbrooke, better known as the Hon. Robert Lowe, in the Reform debates of 1866 and 1867, after the passage of a bill for the extension of the suffrage, uttered the well-known words, "We must now, at least, educate our masters." The same sentiment had also more recently been embodied in the inscription on the Boston Public Library, "The commonwealth requires the education of the people as the safeguard of order and liberty"; and in the presidential address of Dr. J. M. Bodine, at the meeting of the Association of American Colleges in 1897, we find the same idea thus expressed: "In America the citizen is king. The king must be educated to wield aright his ballot sceptre." For many years educators looked upon their work with no little complacency. The educational systems of the various civilized countries were supposed to be well adapted to the ends in view, and educational exhibits had generally been regarded as important features of international expositions; but within the memory of most of those now before him times of serious discontent had not been wanting. Education had not always been found to furnish the required safeguard for order and liberty. Highly educated men had often been found singularly lacking in mental balance. Schools for the inculcation of "common sense" have never yet been established. Even the great developments of psychology as an experimental sign had occurred chiefly within the last twenty-five years; though it had served to establish many a law of mental action, it had thus far failed to justify the hope that pedagogy might find in psychology a foundation for the erection of rational systems of education. Indeed, we had recently been told by one of the ablest expounders of the science that "it was a great mistake for teachers to think that psychology, being the science of the mind's laws, was something from which they could deduce definite programmes and schemes and methods for immediate school-room use. Psychology was a science and teaching was an art; a science only laid down lines within which the rules of the art must fall, laws which the follower of the art must not transgress, but what particular thing he should positively do within those lines was left exclusively to his own genius." Even this general guidance had been very imperfectly afforded, for the limits set by the science of psychology to the art of teaching had never been precisely defined. In fact, the most fundamental question of all, namely, the relation of mental to physical development, had not yet been settled, though much material for its study had been collected. It was not, therefore, surprising that in many countries teachers had made too great demand upon the time and strength of growing children. This had been clearly the case in some parts of Germany, where school-boys from eight to fifteen years of age had found their vital energy so far exhausted by the school work required of them, that they had lost all inclination for the vigorous athletic amusements so naturally indulged in by Anglo-Saxon boys. The deterioration of the race as a result of too close application to intellectual pursuits to the neglect of the physique had been fortunately obviated, in the case of Germans, by the army system, which took entire possession of the youth and forced him to devote three years to the education of his body, turning him out at the end of that period a young man with mind and body trained to a high degree of efficiency, well fitted for civil as well as military pursuits, and comparing favorably in all respects with men of his age in other nations. Looked at from this point of view, the German army must be regarded as an important part of the educational system of the country, though as a piece of educational machinery its workings could not be considered economical. In fact, the absurdity of depending upon the army to remedy the defects of the school system had long since been forced upon the attention of German educators, and the difficulties above alluded to were now in a fair way to be removed. The relations between the governing body of a university and its medical faculty in matters of administration were often defined by custom and tradition rather than by statutory provisions, and differed very considerably in different institutions. In general, two methods of government might be distinguished. Either the initiatory was left with the teaching faculty, the governing body exercising a veto power, or the governing body acted directly without necessarily asking advice from the faculty or its members. The former method of government was most likely to be found in those cases in which a well-established medical school had allied itself to a university for the sake of the mutual benefits that might ensue from the union, and the latter method in those cases in which a university had completed its organization by the establishment of a medical department. In speaking of the proper distribution of the work of a medical student, Dr. Bowditch said that thirty years ago no such question seemed to have presented itself to the minds of the instructors in medicine. The medical faculties of that time contented themselves with providing each year courses of lectures covering the departments of medicine, as they were then understood, and every student was expected to attend as many of the lectures as he saw fit. Between 1870 and 1880 the fact that there was a natural sequence in medical studies became generally recognized, and graded courses of instruction were established in the principal medical schools of the country. The grading was not, however, carried sufficiently far. Thus instruction in both anatomy and physiology was generally given simultaneously through the whole of the first year, though the knowledge of structure should logically precede a knowledge of function. The time seemed now to have come for taking another step in grading medical instruction, and during the academic year now drawing to a close instruction in the Harvard Medical School had been given in accordance with a plan of which the guiding principles were concentration of work and sequence of subjects.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at the Arlington Hotel, Washington, D. C., May 1, 2, and 3, 1900.

First Day—Tuesday, May 1st.

ABRAHAM JACOBI, M.D., PRESIDENT IN THE CHAIR.

President's Address.—DR. JACOBI, in his opening address, discussed the subject of cardiac murmurs in infancy and childhood. He referred to the rarity of functional murmurs in infants, and reported such a case occurring in a colored child aged thirteen months. In this case the murmur, which was a loud systolic mitral one, could not be accounted for at autopsy. Dr. Jacobi said that extra-cardial murmurs, mostly systolic in children, were very infrequent in infants below two years, because at that early time the heart was larger in proportion, and less covered by the lungs.

Ulcerous endocarditis might not exhibit any murmur, and the diagnosis of this condition was thereby rendered difficult. Proliferating endocarditis might give rise to a systolic mitral murmur in the newly born, which might either last a lifetime, or disappear in time with the growth of the organ, or by absorption, or by progressing compensation. Most murmurs meant organic lesions either in the valves or in the myocardium; in that respect all ages were alike. Among other causes of cardiac murmurs in infancy, aside from the infectious diseases and rheumatism, Dr. Jacobi mentioned contraction or partial obliteration of the mitral orifice, or adhesion of the valve; also persistence of the ductus arteriosus Botalli, and congenital stenosis of the pulmonary artery, or other congenital defects.

A Report of Certain Cases of Tuberculosis which were Apparently due to the Nature of the Soil.—Dr. Richard Cole Newton, of Montclair, N. J., read a paper on this subject, in which he emphasized the fact that while sunlight and life in the open air, and pure milk and a wholesome occupation were necessary and essential to the alteration of the predisposition, so that the bacillus of Koch could not gain a foothold in the human organism, a dry, properly constructed cellar to one's dwelling, which should be built over a pure, well-drained, sandy subsoil, was just as essential. The speaker reported a number of cases in which a high mortality rate from consumption in certain families was apparently due to the unsanitary condition of the residence they occupied.

Dr. Leonard Weber, of New York, said he fully agreed with Dr. Newton regarding the important rôle which sanitary conditions played in the development and spread of pulmonary tuberculosis. Examples of this had frequently come under his observation in New York, where, in certain tenement-house localities, the disease was very prevalent.

Dr. N. S. Davis, of Chicago, said there was no question that the acquirement of tuberculosis was best favored by continuous life in poorly ventilated rooms, which induced imperfect lung exercise. Of course, the hereditary inclination to the disease was also a factor, but in its prevention too much importance could not be placed upon the hygienic surroundings of the individual.

Dr. Charles L. Minor, of Asheville, N. C., said that while the epidemic of "tuberculophobia" raging throughout the country would no doubt react beneficially, there had been no corresponding enthusiasm in the direction of prophylaxis. The public had become frightened, but not in the right way. The tubercle bacillus was practically ubiquitous, and if acquirement of tuberculosis depended solely upon that germ, the human race would long ago have been exterminated.

Dr. Edward R. Baldwin, of Saranac Lake, said that the observations made by Dr. Newton had some bearing upon the bacteriology of tuberculosis. Dr. Ransom, of England, had made some investigations which went to show that moisture was an important factor in the development and longevity of the tubercle bacillus, and he claimed to have demonstrated that this germ actually grew upon wall-paper in a house in which the surroundings were very damp. It was well known, Dr. Baldwin said, that dampness would preserve the vitality of the bacilli for a long time in the expectoration.

Dr. Judson Daland, of Philadelphia, said that in Iceland, where all the factors existed which were regarded as favorable to the rapid spread of pulmonary tuberculosis, *i.e.*, long periods of dampness, wind, and absence of light, the disease was practically unknown there until about six years ago, when a few cases of tuberculosis were introduced into the island. Since then the disease had made rapid strides there, and two years ago one hundred and thirty-four cases were reported.

Dr. E. O. Otis, of Boston, called attention to the excellent work in the direction of sanitary improvement which was being done by tenement-house reform committees in New York and Boston.

The Educational and Legislative Control of Tuberculosis.—Dr. Charles Denison, of Denver, read a paper with this title, in which he confined his remarks principally to the degenerative results of deficient ventilation, and secondarily to the degenerative results of defective heredity. In the defective ventilation of living-rooms, the author said, we had a unified, predisposing cause, anterior to the tubercle bacillus, which would explain alike the origination of tuberculosis in animals, fowls, and man; this factor induced deficient pulmonary air and blood circulation, and led to auto-infection. We might reason, as with few exceptions everybody did, that the bacillus of tubercle, being the constant accompaniment of the decaying process in tuberculosis, was consequently the cause and source of all this evil; but the very lateness of its appearance showed it to be rather a result than a cause. Its absence in so many forms of scrofula, adenoid growths, wasting, and catarrhal conditions which eventually proved tuberculous, showed that the pretuberculous and perhaps the first stage of tuberculosis was already established, presumably in advance of the germ. These conditions were proved by the tuberculin test to be a part of the real disease before the microscopic or any other ocular demonstration of the bacillus was possible. Tuberculosis would not "down" in response to any edict against street expectoration, the disinfection of rooms occupied by consumptives, or even the slaughtering of tuberculous cattle, however important these measures of prevention most assuredly were. To show a unified cause, we must come back to the living-room of a human being, the meagre size of which, and its deficient sunlight and air circulation, afforded a sufficiently marked degree of deficient ventilation to constitute a glaring fault of our civilization. This seemed to be the initial cause or starting-point of tuberculosis, which probably killed more people than did war and any other one form of disease together. The speaker said that if law could protect life, as it aimed to do, by fire-escapes, the necessity of stand-pipes, the abatement of the smoke nuisance, the ventilation of sewers, and the non-pollution of drinking water, why should not this subtler and ever-present cause of degeneration and death, defective ventilation, even in its slighter degrees, come under its fostering care? He suggested that an effort should be made to establish and maintain the equivalent of the following, to wit: for a living apartment a minimum space of fifteen hundred cubic feet per individual, and a minimum ventilation or change of air of two thousand feet per hour per person. Furthermore, a course for the study of ventilation should be made a prominent feature of all advanced schools and colleges.

Dr. Beverley Robinson, of New York, said that while the building of sanatoria for consumptives would, no doubt, result in much good, such institutions could do very little toward checking the spread of the disease so long as the more important factors of defective ventilation and hygiene were neglected. A patient was perhaps cured at such a sanatorium, and then must go back to live under the very conditions which induced the disease.

Dr. Carroll E. Edson, of Denver, reported an instance in which the family physician, a man of standing and reputation, insisted upon the discharge of a governess when he learned that ten years before she had spent some time in Colorado on account of some apical trouble from which she had entirely recovered.

Dr. W. F. R. Phillips, of Washington, D. C., said that the subject of "live" air, and devitalized air, to which Dr. Denison had referred, had been extensively studied by Richardson, Mitchell, Billings, and others, and was still unsettled. Richardson came to the conclusion that the devitalization was probably due to some molecular change which occurred in the oxygen. The others attributed its injurious effects to increased temperature and humidity, and to some extent to the carbon dioxide it contained.

Some Phases of the Tuberculosis Problem in Colorado.—Dr. Sherman G. Bonney, of Denver, read a paper on this subject. He stated that there existed in Colorado at the present time not only an appreciation of the communicability of tuberculosis and the necessity for rational preventive measures, but also, unfortunately, a somewhat unreasoning fear as to the dangers of direct infection. There had developed an increasing popular prejudice against ordinary association with the consumptive, and a beginning sentiment against the further importation of individuals afflicted with the disease. The agitation originally conceived through scientific knowledge applied to public health was giving birth to a somewhat ill-proportioned and ignorant crusade. While the percentage of deaths from tuberculosis contracted in the State of Colorado had been progressively increasing during the past four years, the actual number of cases originating in the State was but slightly larger, and the total was considerably less. Thus, in 1893, the total number of deaths from tuberculosis was reported as four hundred and thirty-five, of which forty-nine were specified as contracted in Colorado, establishing the proportion of eleven and one-quarter per cent. The next year the total was three hundred and seventy-seven, a diminution of fifty-eight, while the number contracted in Colorado was fifty-one, an increase of but two cases for the entire year, yet the proportion was published as being 13.7 per cent., a gain of 2.5 per cent. in the deaths originating in Colorado for the year. Despite an increase of fifty thousand in the population of Denver since 1893, the number of cases specified as having developed in 1898 was but four more than in 1893. Dr. Bonney said that a factor of no inconsiderable importance in connection with the question was the strong inherited susceptibility of a portion of the younger population in Colorado, and such infant cases should not be recorded as instances of deaths from indigenous tuberculosis. Another factor was that some residents might develop an active condition from an infection previously latent. On the other hand, he said, it must be remembered that the influx of consumptives in all stages of the disease, and in every condition of financial distress, constituted an economic problem not to be ignored. Many came to the State as a place of last resort.

Dr. Otis said that last year—which was the first year in which the Massachusetts State sanatorium was in operation—sixty-four per cent. of incipient cases of tuberculosis and thirty per cent. of all cases were discharged as arrested. If other States did as well, the fears of the people of Colorado would soon be allayed.

Dr. R. H. Babcock, of Chicago, said the statistics given by Dr. Bonney showed conclusively that the fears of the people in the State of Colorado were not well grounded. The increase in the number of deaths from tuberculosis originating in the State had been insignificant, and could, no doubt, easily be explained on the grounds of environment, occupation, and heredity. The population of Denver had largely increased in recent years, and this was a factor which had favored an increase in the number of cases of tuberculosis.

Dr. James C. Wilson, of Philadelphia, referred to the frequency with which apparently hopeless cases of pulmonary tuberculosis were sent on long journeys in a fruitless search for health. There was now a growing knowledge among the profession that very frequently efficient climatic treatment could be secured at home.

Dr. R. G. Curtin, of Philadelphia, said that Denver would possibly soon cease to be regarded as a desirable locality for tuberculous patients. It largely owed its popularity to the dry climate, which was being altered by the extensive irrigation of lawns and trees, the frequent street sprinkling, the increase in the population, and the number of factories.

Dr. Denison spoke of the prevalence of cases of tuberculous meningitis in Denver. He attributed the slight increase in the number of cases of tuberculosis originating in the State to the fact that many of the residents had a tuberculous family history.

Dr. James A. Hart, of Colorado Springs, said that five yeas ago he announced that he had observed but one case of tuberculosis in his private practice originating in Colorado Springs. Up to the present time he had none others to report.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifteenth Annual Meeting, Held in Washington, D. C., May 1, 2 and 3, 1900.

Edward G. Janeway, M.D., of New York, President.

Second Day—Wednesday, May 2d.

The Organism and Lesion of Actinomycosis.—Dr. J. H. Wright, of Boston, read this paper, which was illustrated by stereopticon views of microphotographs of the diseased organs. The disease, he said, frequently went unrecognized and was much more common than generally supposed. He considered it as a subacute or chronic process. He asked what were the "clubs" or rays, and then answered the question by saying that they were degenerated filaments. In the case from which the specimen was obtained, the lungs, kidneys, liver, and even the abdominal wall and vertebra had been involved. One picture showed abscess involving the ventricular wall of the heart.

Diagnosis.—Dr. Wright said that the diagnosis could be made under the microscope by crushing one of the rays. It was not necessary to stain the specimen. The rays were branched, with dark and light spots. Staining was necessary to bring out these spots. He also spoke of the difficulty of obtaining cultures of the ray fungus, which was due to secondary infection. The ray fungus was anaerobic.

Dr. J. M. Da Costa said he thought the use of potassium iodide had an admirable effect upon the disease and even would cause a cure.

A New Pathogenic Fungus (Sporothrix).—Dr. L. Hektoen, of Chicago, read this paper, which was also illustrated by microphotographs. He mentioned the case of a boy, in whom, after receiving a punctured wound of the finger from an iron nail, several nodules appeared at the site of infection and later along the forearm and arm. Cultures were made from time to time, and with the constant result that sporothrix was present. Dr. Hektoen described the sporothrix as occurring in colonies, with central masses from which radiated spore-bearing threads. It was fatal to white rats when injected into the peritoneal cavity, and caused coagulation necrosis. He said that he knew of only three cases occurring in man.

Dr. Simon Flexner, of Baltimore, said that when the sporothrix was inoculated into mice there was an enlargement of the lymphatic glands, followed by general septicæmia.

Dr. Hektoen contradicted this last statement.

Some Conclusions Arrived at after a Study of One Hundred and Ten Cases of Pernicious Anæmia.—Dr. Richard C. Cabot, of Boston, read this very interesting paper. In his cases there had been fifty-seven males and fifty-three females, and only four cases had followed parturition. Late middle life predisposed toward it, as shown by the fact that in eighty-two of his cases the patients had been over forty years of age. He thought that pernicious anæmia was much more frequent than the text-books would lead one to suppose. Some cases had come to him which had previously been diagnosed as tuberculosis. He thought that there was very little if any relation between the menopause and pernicious anæmia. It had nothing to do with syphilis. Hemorrhage was quite common, especially of the nose and gums. He spoke of the striking constancy of the symptoms in almost all of his cases, even in some of his so-called mild ones, viz., muscular weakness, dyspnœa, gastro-intestinal disturbance (paroxysmal diarrhœa). The appetite had been poor in all but three cases, and in these it had been ravenous. In two-thirds of his cases there had been a temperature of 99° to 100° F., and even higher. The urine in fifty-three cases had been normal, while others had had a trace of albumin with granular casts. Nervous symptoms had not been constant. Some cases had had myelitis. As to the blood, the white corpuscles were subnormal; the number of red corpuscles was 2,500,000. The diameter of the white corpuscles was greater than normal. The proportion of lymphocytes was relatively high. Dr. Cabot said that there was no relationship between the symptoms and the blood condition. The average duration of this disease was from one to two years. The longest-lived case he had had was five years. All treatment, he thought, was hopeless, unless the use of laxatives would be of service, working along the line of Hunter's idea, that of gastro-intestinal toxæmia. Dr. Cabot thought that arsenic did little if any good in these cases.

Report of Cases of Pernicious Anæmia with a Special Reference to the Blood Findings.—Dr. Frank Billings, of Chicago, read this paper. He had had nineteen cases, eleven males and eight females. The average age had been forty-six years; the extremes were twenty-four and sixty-two years. He could find no exciting cause. His cases were similar in result to Dr. Cabot's cases.

Clinical Notes on Cases of Pernicious Anæmia.—Dr. Fred. P. Henry, of Philadelphia, reported five cases, and spoke of his theory that the blood of patients with pernicious anæmia reverted to that of the cold-blooded animals.

Dr. H. A. Hare, of Philadelphia, thought that pernicious anæmia was more common than the books would lead one to think. In his experience, men from the country districts had been more susceptible, and those in mining districts, especially in the anthracite district of Pennsylvania, were prone to the disease. He said that he was opposed to the idea of atrophy of gastric tubules in this disease as an etiological factor, and further, he believed in the use of arsenic for such cases. We knew a great deal about the blood in disease, but did not know so much about it in health. He suggested that work along that line would show variation in form, etc.

Dr. William H. Thomson, of New York, spoke of Hunter's theory of this disease being caused by suppuration at the roots of the teeth and in the mouth, and that swallowing the organisms caused the disease. Dr. Thomson said he had a case in which the stomach washings contained streptococci.

Dr. McPhendron, of Toronto, said he had cured two cases. He spoke of blood-serum injections and thought that some improvement had followed their use.

Dr. S. Weir Mitchell said that all the blood counts that had been given were merely relative and not absolute. Massage increased the number of red cells, or rather brought them out of their hiding-places. He cited his own case as an example.

Dr. Charles G. Stockton, of Buffalo, said that he had had twelve cases of this disease, and laid stress upon the difference between the gastric secretions with hydrochloric acid in pernicious anæmia and in secondary anæmia.

Dr. W. S. Thayer, of Baltimore, thought that one could not make a diagnosis on the blood count alone.

Dr. J. M. Da Costa spoke of the length of remissions in this disease, which were often very great. He recalled a case of a man who apparently was well for eleven months under no treatment whatever. He also mentioned the case of a sailor treated in hospital who, when he had begun to improve, had been discharged and had gone on shipboard and worked for seven months. He had then returned to hospital to die. Dr. Da Costa spoke of high fever in pernicious anæmia, and recalled cases that resembled typhoid fever in their temperature range.

Dr. Herrick, of Chicago, said that the improvement of symptoms was due merely to a relative increase in the red corpuscles and in the percentage of hæmoglobin.

Dr. Cabot, in closing, answered Dr. Hare by saying that counts of normal blood had been made at the Massachusetts General Hospital for the last eight years with negative results.

Proliferation and Phagocytosis.—Dr. F. V. Mallory, of Boston, read this paper. The effects of injurious substances were manifested, he said, in the following way: (1) Degeneration of the cells; (2) exudation from blood-vessels; (3) proliferation of the cells; and (4) phagocytosis. He said that the last two were of importance. He thought that toxins caused proliferation, *i.e.*, strong toxins caused necrosis and death, while weak toxins caused proliferation and phagocytosis. He spoke of the micrococcus lanceolatus causing proliferation (fibrous exudation) in the lungs and kidney. The toxins of typhoid and tuberculosis were mild, and would cause a proliferation of endothelial cells in the blood-vessels of the intestines, or in the liver and spleen. Dr. Mallory said that certain toxins would cause such a great increase of the lymphatic and plasma cells circulating in blood that they would pass out into the organ, as, for example, the kidney, and interfere with its function.

Dr. William H. Welch, of Baltimore, said that he objected to the theory that external agents such as toxins would cause cells to multiply. He thought that the toxins excited necrosis directly, and the finding of bacteria in the larger cells went to show that the smaller cells had attacked the larger ones, and not vice versa.

Cases of Diarrhœa Associated with the Presence of Strongylus Intestinalis in the Stools.—Dr. W. S. Thayer, of Baltimore, read this paper. After spending a short time in giving the history, together with a short outline of its morphology, he reported two cases. The first was of special interest from the fact that the patient had an abscess of the liver due to an amœba coli infection. It had also been infected by infusoria and strongylus intestinalis. Dr. Thayer said that the diarrhœa was never accompanied by pain.

(*To be concluded.*)

Do Not unjustly blame the local anæsthetic for signs of collapse or fainting when the patient is watching an operation upon himself. It is better to cover the patient's eyes even in trivial procedures, and never to operate upon a standing patient.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 19, 1900.

William H. Thomson, M.D., President.

The Physiology of Internal Secretions.—Prof. W. H. Howell, of the Johns Hopkins University, read a paper on this subject. A large number of experimenters, he said, had endeavored to prove the antitoxin theory of the action of such glands as the thyroid, but the accumulated experience of the past few years had apparently made this theory improbable. The very gratifying therapeutic results with the extracts of the thyroid gland had not been paralleled in experiments with the other gland extracts.

Ovarian Extract.—The value of ovarian extract in the treatment of amenorrhœa and dysmenorrhœa seemed to have a rational basis. The hypothesis that the ovaries produced an internal secretion had received some support by recent investigation. For example, experiments had been made upon dogs to determine the effect upon metabolism. After the performance of a double ovariotomy no change in metabolism had been noted for ten weeks, but after that time a decided decrease had been observed in the daily consumption of oxygen. On the other hand, data were available to show that the administration of ovarian extract had increased the daily consumption of oxygen. By the method of grafting more hopeful results were to be looked for. As to the nature of the specific substance of the internal secretion, nothing was as yet known.

Testicular Extract.—With regard to the testicles the evidence that they produce an internal secretion was less convincing. It had been stated by some investigators that castration diminished the consumption of oxygen, but, unlike the ovarian extract, it had not been shown that the testicular extract had the power of increasing the oxygen consumption.

Thyroid Gland.—The parathyroids were minute bodies adjacent to, or embedded in, the thyroid gland. Histologically they showed no resemblance to thyroid tissue. Experimental research indicated that these bodies had a function of their own resembling, in some respects, that of the thyroids proper, but differing in important particulars. Experiments on animals seemed to show that if both thyroids were removed and the parathyroids left, the animal would not die, but death would ensue if both the thyroids and the parathyroids were extirpated. From physiological experiments there was little reason to believe that the functions of the two bodies had anything much in common.

Suprarenal Gland.—Schaeffer had suggested that these glands gave off slowly to the blood an internal secretion which tended to keep the muscular system in proper tone, and particularly the musculature of the circulatory system. It had been shown that the quantity of secretion given off to the blood could be influenced by stimulation of the splanchnic nerve. It had also been demonstrated conclusively that the adrenal vein contained more of this secretion than the other veins of the body. It was exceedingly probable that the active principle of this internal secretion had been isolated in the substance known as epinephrin. This active principle was so easily destroyed in the body that it was hardly probable that therapeutic results of much importance would follow its hypodermic use or its ingestion by the mouth.

Pancreatic Gland.—When the duct of the pancreas is filled with paraffin, an animal showed marked disturbance of nutrition, but beyond a temporary glycosuria there was nothing observed. If after the complete removal of the pancreas a small portion was implanted under the skin of the abdomen, the glycosuria failed to appear, or was slight and transitory. It must be supposed, therefore, that under normal conditions the pancreas gave off an internal secretion to the blood, which was in some way a necessity to secure the normal consumption of sugar. In severe pancreatic diabetes the glycogen disappeared from the liver at the time when there was the most sugar in the urine. Even in the severest form of pancreatic diabetes it was easy to increase still further the quantity of sugar in the urine by puncture of the medulla. Physiological experiments indicated that pancreatic diabetes could not be treated successfully by the ingestion of pancreatic tissue; on the contrary, it had been proved that the transplantation under proper conditions of pancreatic tissue was successful in ameliorating the condition. It was possible that other glands, like the pituitary body, for example, also manufactured internal secretions. This made the subject of metabolism and nutrition much more complex than it had hitherto been believed to be.

The Physiological Effects of Extracts of Ductless Glands.—Dr. Richard E. Cunningham read this paper. He objected to the use of the ordinary desiccated extracts of the ductless glands, on the ground that there was good reason for believing that they were mixtures of various substances, and that the determination of the results from their use must necessarily be very unreliable. Much had been anticipated from the administration of the extract of the pituitary body in cases of acromegaly, yet the clinical results had been disappointing. He had personally been unable to observe the remarkable effects on the circulatory system from the ingestion of suprarenal extract, described by several observers. One would expect the best therapeutic results from the administration of suprarenal extract in Addison's disease, yet the cases so far published had not confirmed this belief. Of twenty-four reported cases that he had collected in which the suprarenal extract had been administered, not a single patient could be said to have been cured, though fourteen had been temporarily improved. Ten had been practically unaffected by the treatment. When the aqueous extract of the suprarenal gland was introduced into the blood-vessels, it caused a marked fall in the blood pressure, but if the colloid preparation of the extract of this gland was injected this lowering of the blood pressure was not noted.

Thymus Gland.—The thymus gland had been first introduced to the medical profession as a remedial agent in connection with the treatment of a case of pseudo-hypertrophic paralysis. In ten cases of exophthalmic goitre treated by him with dried thymus, only three could be said to have been even temporarily improved. The best results from the use of these extracts had been secured with thyroid extract. If large doses of the desiccated extract were given, the results would often be the development of symptoms apparently indicative of poisoning with the proteid bodies constituting the impurities of the extract. On the other hand, it would often be found that the same individual could take rather large doses of iodothyrin without experiencing any such toxæmia. The iodothyrin did not seem to be nearly so active as the colloid, from which it could be easily obtained.

Dr. W. H. Bates said that he understood that the secretion of the suprarenal gland was stored up in the muscles, giving them, as it were, latent energy. In cases of heart disease, a very decided effect on the heart could be observed when the suprarenal extract was absorbed through the mucous membrane of the mouth, or was given hypodermically. This action was less likely to be observed if the extract was swallowed and was thus exposed to the gastric juice.

Dr. Cunningham spoke of the parathyroids, and said that in the dog there were usually two such bodies. The inner one of these was removed with considerable difficulty. In three dogs he had performed the experiment of taking the thyroids and parathyroids and sewing them in an artificial pocket of membrane. All three animals had become myxœdematous. One had been killed at the end of a month, and two had died in the course of another month. He was sure he had removed the parathyroids as well as the thyroids, and yet the animals had survived.

Dr. Howell, in closing, said that Dr. Bates' theory about the storing up of the adrenal secretion in the muscles was not in accordance with the facts brought out by experimentation. Undoubtedly the extract had an effect upon the heart and circulation; nevertheless this was very temporary. The effect of injections was certainly not promising so far as direct physiological experiment was concerned.

SECTION ON MEDICINE.

Stated Meeting, April 17, 1900.

E. Franklin Smith, M.D., Chairman pro tem.

The Iodide Treatment of Aneurism.—Dr. Louis Faugères Bishop read this paper. He said that the immediate effect of this treatment was that the patients were made more comfortable, the pulsation of the aneurism became less, and the sac apparently diminished in size. This remedy seemed to have an effect on the sac itself, whereby the development was less rapid and the tendency to coagulation was increased. The iodide treatment was directed against the tissue changes which were the original cause of the disease. Iodide certainly had a greater influence over tissue metabolism than any other drug. All the other methods of treatment by inducing coagulation had the defect that they sought to cure a disease the causes of which remained active. He had been accustomed to begin the treatment by the administration of ten drops of the saturated solution of iodide of potassium, three times a day, and increasing the dose one drop each day. The speaker said that he had seen so many cases of aneurism benefited by the iodide treatment that he had now great confidence in it. These remarks were intended chiefly for cases of thoracic aneurism.

Report of Three Cases of Thoracic Aneurism in which Subcutaneous Injections of Gelatin were Used.—Dr. Lewis A. Conner made this report, giving his own experience with the method during the past year. Briefly the method consisted in injecting 200 c.c. of a 2.5 per cent. solution of gelatin into the subcutaneous tissues of the thigh, and after the injection keeping the patient absolutely quiet. These injections should be repeated weekly until fifteen or twenty had been given. In his own cases the initial injection had consisted of a two-per-cent. solution and the subsequent ones of a one-per-cent. solution. The injections had all been followed by slight local discomfort and rise of temperature. The first case was one in which rupture took place in the course of the treatment, and the autopsy had revealed no evidence of recent clot formation. The second case had been one of aneurism of the transverse and descending portions of the arch of the aorta. Between May 24th and July 27th seven injections had been given, and each injection had been followed by severe pain lasting often for eight or ten hours. This had been associated with reddening of the skin, but in no instance had suppuration occurred. The pain had been equally severe whether the injection had been given in the thigh or in the abdominal wall. After the second injection the slight pulsation that had been felt posteriorly disappeared. The patient's cough and the irritation of the throat disappeared while under treatment, but the latter had been discontinued because of the great suffering produced. The third case was one of aneurism of the transverse portion of the arch. Three injections had been given, and had caused local distress without producing any improvement. During the treatment there had been a gradual increase in the size of the aneurism. The greatest care had been taken in the preparation of the gelatin solution.

Dr. C. H. Lewis said that he had tried the method in one case, a patient in Columbus Hospital. There had been a very large pulsating aneurism of the arch of the aorta, and extensive erosion of the ribs. The first gelatin injection had caused a good deal of pain and some rise of temperature. At the expiration of a week a second injection had been given, but it had also been followed by severe pain and by a temperature of 103° F. A few days later the aneurism had ruptured. Unfortunately an autopsy could not be obtained.

Rabies in New York City.—Dr. Robert J. Wilson read a paper with this title. He deplored the tendency of certain physicians to deny the very existence of rabies, because this led students and young physicians to be careless in the treatment of animal bites. In 1898 there had been eight cases of death from rabies in the Greater City of New York; in 1899 two cases, and so far in 1900 one case. The disease might be said to be endemic in the borough of Richmond. Since January 1, 1897, the bodies of forty dogs had been received at the laboratory of the health department, four coming from one locality. Mild and superficial cauterization, or the application of antiseptics, was worse than useless. The best application was the actual cautery. Fuming nitric acid was about as good, but the wound left by it was slower and more troublesome in healing. Unless the wound was very insignificant it was better to administer an anæsthetic in order that the cauterization might be thoroughly done. Such a procedure conferred protection in about ninety per cent. of cases. In all suspected cases the best treatment should be instituted whenever possible, and if this was done it would yield ninety-nine per cent. of successes. The shortest period for the Pasteur treatment was fourteen days, but it was often necessary to extend the treatment over a period of eighteen to twenty-five days. The injections were preferably given over the abdomen. The first few injections were quite painful, but it was possible for an individual who was not of a nervous temperament to take the treatment and still continue at work. There was absolutely no danger in the treatment itself, but it was not advisable to send the virus out from a central laboratory.

Dr. H. T. Cronk sent a report of a case of rabies that he had observed at the Gouverneur Hospital.

Dr. C. H. Lewis presented the report of the case of rabies which had occurred recently at St. Vincent's Hospital. On March 8th a man, sixty years of age, had presented himself for treatment for a bite on the right side of the neck and cheek which he had received from a strange St. Bernard dog. This dog had been found by the man's children, and had appeared perfectly docile, so that the family had been on the point of keeping the dog. The man had attempted to remove a string from the neck of the animal, and in doing so had pressed upon a partially healed sore; immediately the animal had sprung upon him and inflicted a wound from four to six inches long. The animal had exhibited thereafter no other signs of distemper or other disease. The dog had been immediately shot by the police, and his carcass taken away by the street-cleaning department. The wound had been irrigated at the hospital with bichloride solution, cauterized with pure carbolic acid, partially sutured, and dressed antiseptically. The man had suffered much pain that night, and on his return to the hospital, on the advice of the surgeons there, he had entered the hospital. Thirteen days after the bite, the patient had been discharged with the wound healed. Twenty-one days later the man had been readmitted, this time to the medical service of the hospital. For eighteen days he had worked, and had felt perfectly well. On April 10th, on attempting to drink some water he had experienced the first difficulty in swallowing. During the night he became nervous and sleepless, and the wound began to pain him. The next morning he had gone to the Pasteur Institute, where he had been told the preventive treatment would be of no avail. On readmission to St. Vincent's Hospital, on the same day, his pulse had been 80, respiration 24, and temperature 98° F. There was a peculiar apprehensive expression, and he begged to have water taken away, although the mere sight of it had no effect upon him; it was only when he was asked to drink it that he experienced any distress. On the following day the temperature had kept at about 102°; the face had been flushed, and there had been some dyspnœa and a feeling of tightness about the throat and chest. That night he had become delirious. In the morning his temperature had been 103°, his pulse 84, and respiration 24, and he had been quite excitable. For the first time medicinal enemata caused spasm. He passed into coma and died at 5 P.M. A partial autopsy had been secured, making it possible to examine the medulla, pons, and part of the cord. Nothing distinctive had been discovered from the gross appearance, but portions of the brain and cord had been taken for purposes of inoculation.

Dr. L. F. Bishop emphasized the importance of teaching that there were two forms of hydrophobia, the rabid and the paralytic. Comparatively few people seemed to know or realize that a dog might have hydrophobia and yet not be rabid, or exhibit the classical symptoms of rabies.

Dr. Wilson said that while he believed no case had been reported in which hydrophobia had been communicated to another by a dog through the saliva alone, nevertheless it was a well-recognized rule in all Pasteur institutes that the utmost care should be taken to use antiseptics, to cleanse all parts from saliva, and to take every precaution against possible contamination of this kind. It was exceedingly important in every case of dog-bite to inquire where the dog had come from, and whether the animal was a stray one. If the latter was the case one should immediately take steps to find out what had become of the animal. He did not think human beings were usually infected from animals suffering from the paralytic form of rabies; indeed, the paralytic form seemed to be wholly restricted to laboratories.

Dr. Lewis remarked that there was a rule requiring the police department to see that every animal that had bitten a person and had been shot should be taken to the health department for investigation. Had this been done in the case just reported it might have been the means of saving the man's life.

Dr. L. A. Conner said that some years ago the assistant pathologist of the New York Hospital had died shortly after having made a post-mortem examination on a case of hydrophobia. He had presented in his last illness a peculiar form of paralysis which had been considered at the time to be paralytic rabies.

The Good and Bad Effects of Digitalis Used as a Therapeutic Agent.—Dr. William Henry Porter read a paper with this title. He said that it was quite apparent from a perusal of current literature that the action of digitalis upon the human system was not yet fully understood; hence he desired to present in this paper a review of its physiological function and therapeutic possibilities. To comprehend thoroughly the action of any drug its chemical composition must be fully understood. So far, five glucosides had been isolated from digitalis, viz., (1) digitalein; (2) digitoxin; (3) digitonin; (4) digitalin, and (5) digitin. They were all oxidizable substances, and yielded as the result of their oxidation-reduction heat, carbonic acid, and water. Only four of these glucosides actively influenced the animal economy, and while three of these had actions in common, the fourth was absolutely antagonistic to the other three.

Powdered Digitalis.—When powdered digitalis was administered the contained active principles profoundly influenced the action of the heart and the circulation. The three active principles which had a similar action caused a short and more intense systole and a prolonged diastole, and at the same time, by contracting the arterioles, produced a decided rise in the blood pressure. These circulatory changes were immediately followed by a marked slowing of the heart's action—an effect which was best explained by the increased resistance in the arteries and the depressing effect of the digitonin upon the cardiac muscle. If the digitalis was continued, the cardiac pulsation became more frequent and feeble as a result of the toxic effect of all the active principles of digitalis on all the involuntary muscles. While these changes were taking place the continued high arterial tension deprived the heart of its proper nutrition, so that if the drug was not withheld, the final result would be death with the heart in diastole. As a rule, the blood pressure in the splenic arcade remained normal.

Infusion of Digitalis.—The effect of the infusion of digitalis is different from that of the powder because two of the active principles, digitoxin and digitalin, were almost wholly insoluble in water. The infusion, therefore, really contained only two active principles, digitalein and digitonin, whose actions were antagonistic.

Tincture of Digitalis.—Still another action was observed from the use of the tincture of digitalis, because while digitoxin and digitalin were freely soluble in alcohol, digitalein was only sparingly soluble, and digitonin not at all.

Fluid Extract of Digitalis.—The fluid extract more closely resembled the powder in its action, but it was a more uncertain preparation because there was no practical method of determining just what proportions of the different ingredients were dissolved out by the mixture of alcohol and water used in preparing the extract.

Cumulative Action.—Dr. Porter said that careful study failed to discover good evidence that digitalis was stored up in the system for a time and was then suddenly liberated and eliminated, thus giving rise to the well-known phenomena attributed to the so-called cumulative action of this drug. This action appeared to be more directly exerted upon the heart, the kidneys often acting freely even in spite of the depressed heart action. The explanations hitherto advanced seemed to the speaker wholly inadequate. His own explanation of the occurrence of these symptoms of digitalis poisoning was, that three factors were at work, viz., (1) the diminished nutritive supply to the cardiac muscle, resulting from high arterial tension; (2) the increased work imposed upon the heart, and (3) the direct action of digitalis as a powerful muscle poison. He said that there could be but one result of the continued administration of digitalis, *i.e.*, the degeneration of the muscular fibres of the auricular and ventricular walls, particularly of the former. The heart action was at first slowed to meet the increased demands made upon it; then, like any other degenerated heart, its action became rapid and feeble, and finally irregular, or it might stop altogether in diastole as a result of some slight exertion, such as sitting up in bed or rising to pass urine. When a reliable preparation of digitalis was administered continuously up to the full physiological limit, the heart was invariably damaged, thus explaining the oft-repeated remark that digitalis proved unsatisfactory in permanently alleviating cardiac affections.

Digitalis in Mitral Lesions.—When there was insufficiency or stenosis of the left auriculo-ventricular orifice, digitalis temporarily improved the condition. In the case of aortic insufficiency, digitalis caused a more rapid and effectual closure of the incompetent orifice, and, by the intensified systole, a more thorough emptying of the ventricle. In cases of mitral stenosis the prolonged diastole and intensified contraction of the auricle enabled the latter more thoroughly to fill the ventricle, and the more powerful systolic contraction drove a larger volume of blood into the aorta. It was evident, therefore, that in both lesions of the mitral orifice the administration of digitalis overcame the pulmonary congestion and the dyspnœa dependent upon it. But once the normal tension had been reached and passed, the action of digitalis was detrimental to all the physiological functions of the body.

Digitalis in Aortic Lesions.—Dr. Porter said that there seemed to be no good reason for the employment of digitalis in cases of aortic insufficiency or aortic stenosis. In aortic regurgitation the increased systole certainly could not compensate for the prolonged diastole, and the longer time during which regurgitation could take place, to say nothing of the injury resulting from increasing the peripheral resistance and diminishing the nutritive supply of the cardiac muscle. In aortic stenosis the augmented cardiac systole might, for a time, force a larger volume of blood into the aorta, but the increased work thrown upon the heart, the toxic effect of digitalis on the muscle, and the progressively diminishing nutrition soon led to degeneration of the heart, and to an aggravation of all the symptoms. In fatty degeneration, or in any enfeebled state of the circulation in the heart muscle, digitalis was contraindicated. In hypertrophy of the heart digitalis might possibly be of use for a few days at a time in cutting down the nutritive supply, but it was too dangerous a remedy to employ for such a purpose. Digitalis should be given to influence the heart and circulation only when the arteries were very much relaxed, and the pulmonary or systemic veins overfilled. As soon as the engorgement had been relieved, digitalis should be stopped, and more reliable remedies substituted. It was true that some of the bad effects of digitalis could be antidoted by combining it with nitroglycerin, but such a combination did not prevent the toxic action of digitalis on the involuntary muscles, and it was at best poor therapeutics.

Action of Digitalis upon the Kidney.—The speaker then proceeded to discuss at length the physiological laws governing renal secretion, and in this connection made the statement that the quantity of water discharged from the kidneys was dependent upon the relation of hydraulic pressure within the glomeruli on the one hand, and in the arterial system throughout the body on the other hand. The function of the epithelial cells lining the uriniferous tubules was a much more complex problem. Serum albumin did not exist in the blood as a single substance; what had been called serum albumin was now known to be composed of three or more isomeric forms of the proteid molecule. The speaker said that it had been asserted that digitalis was not eliminated from the system by the kidneys in the form of glucosides, and hence the diuretic effect of digitalis could not be explained by any irritative action upon the renal glands. It was not difficult to show that the chief action of digitalis on the kidneys could be explained by its power to change the mechanical workings of the heart and of the circulation. When digitalis was administered continuously in rapidly increasing doses, owing to the high arterial tension and the diminished calibre of the renal arteries, the blood was driven through the kidneys so rapidly that the effete material was not removed. The result was first an anæmia, and subsequently a toxic condition usually described as uræmic. In cases of renal disease in which there was no marked swelling of the epithelial cells and the exit from the larger veins remained unimpaired, digitalis simply drove the blood through the kidneys more rapidly without augmenting the hydraulic pressure in the glomeruli, and consequently in this class of cases digitalis had no diuretic action, but impaired the nutrition of the kidney and practically aggravated the kidney lesion. On the other hand, if there was a general venous engorgement, a passive congestion of the kidney, or an active determination of blood to the kidneys until the circulation in them had become impeded, the result was very different. The same was true of all forms of parenchymatous metamorphosis or degeneration of the epithelial cells, for here the latter became swollen and by pressure on the veins outside the Malpighian tufts, prevented the normal and free escape of blood from the efferent vessels of the glomeruli. When digitalis was administered under these conditions, the watery constituents of the blood flowed off through the capillaries of the Malpighian tufts into the uriniferous tubules—in other words, its action here was that of a true diuretic. Moreover, the improvement of the general circulation in this class of cases led to better nutrition in the kidney itself, and in this way helped to cure the parenchymatous lesion and all other lesions found in this group of cases.

Conclusions..—The author's conclusions were as follows: (1) The chemical composition of digitalis is complex, some of its active principles antagonizing others; (2) the various preparations of digitalis differ widely in their composition and action; (3) the so-called cumulative action of digitalis is due to its contracting the arterioles and shutting off nutrition; (4) it is both a useful and a dangerous remedy, and has a very limited range of usefulness; (5) it is of use only in lesions of the mitral valve, and then only for a short time, and should be discontinued as soon as these have been overcome; (7) it is of value as a diuretic only when there are low arterial tension and engorgement of the kidney; (8) digitalis decreases the excretory action of the normal kidney and impairs its nutritive activity.

Dr. Leonard Weber took exception to the statement in the paper that the infusion of digitalis was of but little value. His personal experience with it had been much more satisfactory, provided he used the fresh English leaves, made into an infusion of the strength of half a drachm to six ounces of water. He had been seldom disappointed with it, and had attained as good results as with the powder. He had used Squibb's fluid extract for years, and had found it also an exceedingly useful remedy, being not only reliable and effective, but convenient because of the smallness of the dose. The indications for the use of digitalis had been laid down very clearly in the paper, as had also the action of digitalis on the kidneys. He had been particularly pleased with the statement that digitalis was seldom, if ever, indicated in disease of the left side of the heart. He looked upon digitalis as one of the most valuable remedies at at our command.

Dr. L. A. Conner said, concerning the use of digitalis in aortic insufficiency, that while the indications for this drug were much less frequent here than in some other cardiac lesions, he could not but feel that it sometimes proved exceedingly beneficial. The theoretical objection that it unduly prolonged the period of regurgitation did not seem to him of much weight, for, if this argument was carried to its logical conclusion, it meant that we should make use of remedies which would increase the rapidity of the heart's action. It was a question rather of the condition of the ventricle and of the state of the heart muscle than a theoretical consideration of the purely mechanical problems involved.

Dr. Porter, in closing, said that his statements had not been made from a purely theoretical standpoint, but had been based on a very large clinical experience. This had been that, outside of that condition in which there were decided venous engorgement and emptiness, so to speak, of the arterial side of the system in cases of aortic regurgitation, digitalis was more harmful than useful. The great danger from digitalis was from the heightening of the arterial tension in the coronary arteries, with the consequent impairment of the nutrition of the heart. He still believed that the tincture of digitalis, made from the fresh leaves, was the most valuable and the most certain of the preparations of digitalis. It contained the largest percentage of those constituents which were most useful in the treatment of cardiac disease.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 23, 1900.

J. Clifton Edgar, M.D., Chairman pro tem.

Tetanus: its Nature and Therapy.—Dr. Alexis V. Moschcowitz read a paper with this title. Tetanus was one of the diseases known from time immemorial. It was an acute infectious disease, invariably caused by the entrance into the body of the organism of Nicolaier. Different names had been given to this disease, but they were really varieties of tetanus, giving rise to differences in symptomatology. Tetanus might follow the slightest injuries, such as the introduction of a hypodermic needle, or from a leech-bite. The diagnosis was readily made by finding the bacillus of Nicolaier.

Etiology.—It was caused by the lodgment of the bacillus of Nicolaier, except in the few cases in which the tetanotoxin or other poison resulting from the action of the bacilli had been introduced into the system in laboratory work. The germ was harmless when swallowed, inhaled, or introduced into the rectum.

Symptoms.—The symptoms were always so well marked that the reader of the paper did not enter largely into the description of them. Cephalic tetanus began with paralysis of the muscles supplied by the facial nerve. Puerpural tetanus might follow abortions as well as child-birth. It always began with trismus. Tetanus neonatorum was a disease of the poorer classes, and the first symptom was inability to nurse.

Pathological Anatomy.—It was difficult to give the concise pathological anatomy of tetanus; it was not fully known. The present knowledge of its pathogenesis pointed to the cells of the anterior horns as the seat of changes. Local tetanus occurred regularly in all cases of experimental tetanus and in muscles nearest the seat of infection. The seat of origin of the spasms was in the spinal cord, the toxins being carried along the nearest nerves. The peripheral nerves which were connected with the wound were frequently in a condition of acute, septic, ascending neuritis.

Prognosis.—The prognosis depended upon two factors: (1) The period of incubation; (2) the rapidity of the symptoms showing the progress of the disease. The prognosis of acute tetanus with a short period of incubation may be as high as 96 per cent., down to 60 per cent., or a trifle less. During the past ten years the following cases, taken from the literature, gave these results: From the use of the subcutaneous method, 290 cases, of which 173 resulted in recovery; from the use of the intracerebral method, 48 cases, in which 23 patients recovered; or a total of 338 cases, of which number 196 patients recovered and 142 died. He separated the cases into the following divisions: (1) Very grave cases, in which, in one or two hours, the whole body would be involved; (2) grave cases, in which the tetanic symptoms were continuous, tonic and clonic convulsions taking place; (3) medium grave cases which developed in the course of a few hours to six weeks, and in which the symptoms gradually disappeared; (4) mild cases, which were distinguished by the symptoms coming on gradually; (5) very mild cases, in which there were mild trismus and mild rigidity of the muscles of the neck; here the symptoms might last many weeks.

Treatment.—Up to the last decade the treatment was symptomatic. By the efforts of Cattani, Tizzoni, and others the treatment had been modified. The rational treatment embraced the following points: (1) The bacteria should be destroyed at the seat of infection; (2) the toxins already absorbed should be eliminated; (3) an endeavor must be made to render innoxious the products absorbed; (4) the symptoms induced by the action of the toxins should be overcome. The offending body should be removed and the wound disinfected. Saprophytic germs were easily destroyed. A solution of bichloride, 1 : 1,000, to which was added five per cent. of tartaric acid, might be used. Tincture of iodine was useful. The entire wound should be cauterized with the actual cautery or nitrate of silver. Amputation of the injured member might have to be considered. In endeavoring to eliminate the toxins already absorbed, it had not yet been definitely decided through what channels the toxins were eliminated. He advised the use of diuresis, catharsis, and diaphoresis; these were certainly worthy of trial on theoretical grounds. Again, a certain quantity of blood might be withdrawn and decinormal saline solution introduced. The fundamental principle of treatment was by means of introducing into the system the serum of animals rendered immune; the mode of action had not been acceptably explained. He referred to the failure to diagnosticate tetanus sufficiently early. A patient with tetanic symptoms was not beginning to have tetanus, but was beginning to die of tetanus. The toxins should be neutralized; their effects on the body should be prevented. The intracerebral injections he thought to be devoid of danger if used with proper antiseptic and aseptic precautions, and done slowly enough. Urticaria had been observed, but it disappeared within a few days. As to immunizing the patient after infection had taken place, this involved the introduction of the antitoxin as a prophylactic measure in all wounds; such opportunities were seldom offered. To overcome the symptoms induced by the action of the toxin, the reflex irritability of the higher reflex nerve centres, the aim should be to take such measures as will prevent spasm, as by the use of certain remedies. Of some value were opium and morphine, chloral, bromides in full doses, hyoscyamus, physostigma, etc. The injection of certain emulsions into the brain substance was referred to; also the destruction of the toxins circulating in the system by injections of carbolic-acid solutions. In closing the speaker stated that by the antitoxin treatment the mortality had been reduced from ninety per cent. to about forty per cent. He recommended that, although the serum was of great value, the other therapeutic measures should not be neglected.

Dr. William H. Park said that the first surgical point to keep in mind was how extremely local was the poison of tetanus; the bacilli, and the toxins that originated from them, were to be found in the small local wound; so, if the case was seen early enough, much of the symptoms could be eliminated. He emphasized the importance of cleansing the wound in order to get rid of both bacteria and the toxins.

Dr. Lambert did not get with the serum treatment as favorable results as were given in Dr. Moschcowitz's paper; he was not much encouraged from the use of the serum. Regarding the method of treatment he did not see that better results were obtained when the serum was introduced into the ventricles or spinal cord than when an intravenous injection was given. Cases had been reported in which patients had died from abscess of the brain and not from the tetanus. The intravenous and subcutaneous methods should be tried, and he cautioned against injections into the brain or spinal cord.

Dr. Robert Abbe stated that, from his personal experience with the antitoxin, he rather favored its use and would certainly use it again under similar circumstances. Up to summer before last he had seen only six cases, and these, with one exception, had been fatal. Two years ago he had seen two, and last summer he had seen seven cases. Two cases he had treated by the subcutaneous method; he had had a small allowance of the serum, and bad results followed. Last summer he had seven cases which presented unusual and interesting features; they furnished a valuable opportunity to see differences in action in wounds in which the tetanus poison had gained an entrance; the wounds acted as differently as two surgical wounds could. Some of the wounds were not ordinary suppurative ones but ugly punctures, following pistol shots, and around the wound, in an area as large as the hand, there was a lardaceous infiltration; when it was incised it cut like pork. All wounds should be thoroughly cleansed, and he preferred the tincture of iodine for this purpose, wetting a cloth with it. The intracerebral injections were used only in bad cases; in five such cases three patients survived. The method used was that of Kocher; a simple open wound was made by drilling through the bone with a common hand-drill, and the antitoxin was injected with an ordinary hypodermic syringe. An opening as large as a lead pencil could be made under cocaine anæsthesia; the proper position was half-way between the outer angle of the orbit and a point in the middle of the median line of the skull directly over the auditory meatus. There was no pain or mental change; the pupils, pulse, respirations, and heart were absolutely unchanged. There was no evidence of later trouble so far as could be determined. In two cases the injections were made twice through the same wound. A practical question that presented itself was whether we could see any effect from the direct administration in this way, either immediately or in the future, that could be ascribed to the remedy. In some cases one could not see any striking effects. In some cases there was some decided benefit, even in those that were fatal. In one case of puerperal tetanus that was referred to him, the woman was in an exceedingly bad condition; intracerebral injection by Kocher's method was performed, and the patient went thirty-six hours without spasms; she ultimately died.

Dr. M. W. Ware had often seen the lardaceous appearance of the wounds described by Dr. Abbe, occurring about the injuries from guns or toy pistols. Knowing that the germ of tetanus was anaerobic, he incised three inches away from the wound in patients who had died from this disease, and he got pure cultures. This taught him that, in these cases of tetanus, it was better to lay open widely the wounds when first seen. He deprecated the use of caustics on account of the eschars that were formed.

Dr. Alexis V. Moschcowitz closed the discussion. Regarding the remarks of Dr. Park, who had stated that most of the patients had died after intracerebral injection from abscess of the brain, as a matter of fact he had collected all of the cases in which the intracerebral injection had been used, and only one patient had died, and in this instance the streptococcus albus was found, showing that it had resulted from improper cleansing of the skin; that patient probably had general sepsis. Injury to the brain might be done, but not if care was taken to use a fine needle and to take enough time.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 5, 1900:

	Cases.	Deaths.
Tuberculosis	214	164
Typhoid fever	13	2
Scarlet fever	152	13
Measles	637	32
Diphtheria	233	30
Laryngeal diphtheria (croup)	8	6
Cerebro-spinal meningitis	0	4
Chicken-pox	26	0
Smallpox	2	0

Yellow Vision after Snake-Bite.—Richard Hilbert mentions the various conditions attended with the phenomenon of colored vision. So far as he is aware, his is the first report of seeing yellow after snake-bite. A young girl, walking barefoot in the fields, fell with a piercing cry that she was bitten on the toe by a snake. The snake was seen by others. An hour later, when brought to the office, blood could be squeezed from the wound near the nail. The limb was 5 cm. greater in the middle thigh than its fellow, and the calf 4 cm. The next day there were stiffness and pain, besides the symptom that all light-colored objects appeared bright yellow. A bluish discoloration of the skin, extending over the abdomen, required fourteen days to disappear. It was seven and a half weeks before the child was well again. It would be interesting to learn whether in tropical countries, where snake-bite is more frequent, yellow vision is a common symptom.—*Memorabilien*, April 3, 1900.

Notes on a Case Simulating a Perforating Gastric Ulcer.—W. J. Thompson and F. C. Dwyer met with the case of a young woman, aged twenty-three years, who some six weeks previously had begun to suffer from vomiting on taking food, with much discomfort and flatulency. After a meal of bread and milk she was seized with nausea and epigastric pain, followed by the vomiting of a reddish fluid. Symptoms grew worse in the course of a few hours, with abdominal distention, rapid and weak pulse, fever, etc., and a diagnosis of perforation was made. Section of the abdomen revealed, not a gastric ulcer, as was expected, but a coil of jejunum intensely inflamed, covered with flakes of lymph and having on its surface two patches almost gangrenous, though not yet perforating. Nine inches of bowel were resected, the Murphy button being used. Recovery ensued. The lesion was believed to have resulted from infarction from a mesenteric thrombus.—*Dublin Journal of Medical Sciences*, April, 1900.

WHEN SHALL WE OPERATE FOR APPENDICITIS?[1]

By JOSEPH WIENER, Jr., M.D.,
NEW YORK.
ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

My object in writing this paper is not to add to the already overwhelming mass of literature that has of late years accumulated on this subject, but rather to attempt in a feeble way to let a little light on the most important part of the whole subject-matter, namely, when shall a given case of appendicitis be submitted to operation? In spite of the extensive literature on this subject, perhaps to some extent on account of it, much uncertainty and diversity of opinion exist among medical men as to when they should advise an operation in these cases. I have been led more particularly to be interested in this subject because I am almost daily coming in contact with cases of appendicitis that are sent to the hospital by physicians. Only too many of these patients have already perforations of the appendix, and not a few have a general peritonitis.

I am no firm believer in the value of statistics, but the following figures taken from the annual reports of the Mount Sinai Hospital for the past five years must give food for reflection:

	1894	1895.	1896.	1897.	1898.
Total number of cases of appendicitis.	41	87	91	130	149
Number of cases with general peritonitis	7	10	14	23	22

In one hospital alone we find in five years seventy-six cases of general peritonitis due to disease of the appendix, almost every one of which, of course, terminated fatally. It need scarcely be mentioned that had these seventy-six patients been sent to the hospital early, the large majority of them would have recovered. The term "early operation" is a relative one, and much harm has been done by attempting to lay down rules as to on which day or at which hour after the onset of the attack an operation should be performed. I have known of several cases that were sent to the hospital on the third or fourth day of disease, sometimes even on the second day, with general peritonitis. On remonstrating with the physician of these patients for having delayed so long before sending the patients in for operation, the reply has generally been: "Why, it is only the second or third day of the disease." This was very true, but it generally cost the patient his life. Every case must be decided on its merits—no rule of thumb can be laid down. To wait for symptoms of perforation or of peritonitis is fatal. Patients may die, and especially children do die, from sepsis without any perforation. It is advisable in children to urge operation even earlier than in adults, for the child's heart cannot withstand sepsis as well as an adult's. But there is another important point about this term early operation. When did the disease in the appendix, the appendicitis, actually begin? With the onset of the first attack of pain, vomiting, fever, etc.? Or was there an inflammation going on insidiously long before? The first attack of appendicitis very often does not mean the beginning of the disease. There may have been a catarrhal inflammation, or even an ulceration of the mucous membrane of the appendix for a long time before the onset of what is generally taken for the first attack. The acute attack may mean that the ulcerative process is suddenly increasing, or that a foreign body (coprolith) is superimposed on a previously long-present ulcer; or it may mean that the peritoneum about the appendix is becoming inflamed (a local peritonitis). If we fail to keep these anatomical facts in mind, we will frequently be disagreeably surprised on opening the abdomen early in an attack (as we suppose) to find a perforation of the appendix and a general peritonitis. If, on the other hand, we keep the pathology before us, we will carefully examine the history of every case of acute appendicitis for any gastric or intestinal symptoms which, even though slight, may have previously been present. We will sometimes even get a history of slight pain at times in the right iliac region, for months preceding the first acute attack. In the presence of such a history, we will be more anxious to operate very soon after the beginning of the acute attack. For these are just the cases in which, on opening the peritoneal cavity on the second or third day, we find a diffuse peritonitis. Naturally, this is true to even a greater degree in recurrent attacks. For here we know that a pathological process has been for weeks, or months, or even years, going on inside the appendix. And we do not know, we cannot know, how near that process in the appendix is to perforating. Six hours, twelve hours, twenty-four hours of an acute attack may bring on a fatal perforation, and we may then perform an early operation, so-called, and find to our sorrow that it is a very late one. Hence it will be wise in a second or third attack to operate earlier than we would in a primary attack with the same intensity of symptoms. There is a class of cases in which the patients have one attack of moderate severity that keeps them in bed for a few days only. They then get up and attend to their work, but they often have pain and discomfort in the right iliac region with perhaps some gastric disturbance. These cases, though the patients are able to be up and attend to their affairs, are always dangerous, and cannot be watched too carefully. They go along for weeks or even months, and then there suddenly develops a second attack, which is always a severe one and often fatal. The disease with them is progressing continuously though slowly, and finally leads to a sudden climax. The following case, in which I operated a short time ago, serves as a striking example of this class:

Charles L——, aged seventeen years, had his first attack of appendicitis six months ago. He was in bed for two weeks with moderate pain and tenderness, which were relieved by ice-bag and opium. For the following few months he had pain and discomfort off and on in the right iliac fossa. For the past six weeks he was free from pain until two days before his admission to the hospital, when he was seized with severe general abdominal pain, which soon became localized to the right side. At the beginning of the attack he had a chill lasting ten minutes. He was treated outside for forty-eight hours, and entered the hospital with a pulse of 150 and temperature of 104° F. I decided to operate as soon as I saw the patient, which was about an hour after his admittance. At the operation an enormously thickened appendix was found, gangrenous at its base, where it had sloughed away completely from the cæcum, and surrounded by foul-smelling pus. In the pus a small coprolith was found, and at the tip of the appendix was a second one. The general peritoneal cavity was not invaded at the operation; the appendix was removed and the whole wound packed with gauze. Four hours after the operation the patient had a second chill lasting ten minutes. The day following the operation the pulse rate was 120–142, and the temperature 100°–102° F. There was slight conjunctival icterus and some delirium—in short, the usual picture of sepsis. Septic paresis of the intestines developed, and the patient died in forty-eight hours after the removal of the appendix.

---

[1] Read before the Harlem Medical Association, January 8, 1900.

I operated in a somewhat similar case last summer. A boy, aged seventeen years, had three attacks of appendicitis during the preceding year and a half. The attacks were mild in character, and had kept him in bed only a few days. Between his attacks he had occasionally had slight pain on the right side. He entered the hospital two days after the beginning of the attack, which had been ushered in by vomiting and pain in the right iliac region. There was general abdominal pain, and the whole abdomen was very rigid. The diagnosis of appendicitis with general peritonitis was made. At the operation, offensive purulent fluid was found in the peritoneal cavity; the appendix was perforated at its base, not adherent, but the small intestines were all matted together, presenting the usual picture of a general peritonitis, of which the boy died within twenty-four hours of the operation. Such cases, of which we see only too many at the hospital, have prompted me to write this paper.

The diagnosis of appendicitis is made from: (1) The history; (2) the symptoms; (3) the results of examination—by abdomen, by rectum, by vagina.

As regards the history, we must ascertain first of all whether there have been previous similar attacks, whether the patient has had gastric or intestinal symptoms which may have been passed by as "indigestion," and yet may have been due to trouble in the appendix. The history of the onset of an acute attack of appendicitis is generally one of two kinds. Either there has been general abdominal pain with or without vomiting for some hours, with a gradual localization of the pain to the right iliac fossa—this is the history we most frequently obtain. Or, on the other hand, the attack begins with severe pain on the right side, generally accompanied by vomiting, but with little or no pain in other parts of the abdomen. This history is not so common, and generally speaks for a severe inflammation.

The symptoms of appendicitis are sufficiently well known not to need much dwelling on. I would merely draw attention to the fact that the symptoms are unfortunately very often no criterion of the intensity or character of the disease. We see very severe cases with very mild symptoms; we see mild cases with severe symptoms. The symptoms of an attack may be entirely masked by the treatment that is being instituted; particularly is this true of the use of opium or morphine. Too often is operation delayed because the pain has subsided under the use of opium, and the patient feels very comfortable, while the pathological process in the appendix is quietly progressing. Too much stress cannot be laid on the danger of using opiates in this treacherous disease. Almost all the patients that enter the hospital with a general peritonitis have been treated with opium or morphine. For myself, I firmly believe that if the pain in an attack of appendicitis, in spite of the use of an ice bag, is so severe as to necessitate the giving of morphine, then an operation is almost invariably indicated. Pain and local tenderness are two of our most valuable symptoms in this disease, and we dare not give drugs that will mask them.

It is a mistake to think that the point of greatest tenderness is always near the anterior superior spine of the ilium. True it is that this is generally the case, because that is the usual location of the appendix. But where the appendix is, there will we find the greatest tenderness. If the appendix is located high up near the gall bladder, the greatest tenderness will be in the hypochondriac region. If it is located low down in the pelvis, we will elicit great pain by rectal or vaginal examination. Moreover, it is often true that the greater the pain, the more severe the disease. If a case on one day presents but moderate pain and on the next shows a decided increase, we may safely deduct therefrom that the inflammation has become just so much more severe. Late in the disease, however, sepsis may so blunt the sensibilities that pain is no longer complained of. Perforation of the appendix often causes severe local pain, which after a few hours is decidedly less but more diffuse, showing the beginning of the involvement of the general peritoneum.

The examination in cases of appendicitis is of prime importance. The local symptoms are decidedly more important than the constitutional ones. In the face of marked local signs we should operate even if the constitutional symptoms are slight. Conversely, however, if we have marked constitutional symptoms with but mild local ones, we should not be too quick to operate, but should first be certain that we have a case of appendicitis to deal with. Nevertheless in some of the worst cases we can feel surprisingly little. This is due in great part to the rigidity of the rectus abdominis and oblique muscles of the right side. This rigidity of the muscles is a very important sign, as it usually speaks for a severe intra-abdominal inflammation underlying. How often do we cut through such a rigid abdominal wall and find a perforated appendix! The following case illustrates what an important indication for operation right-sided rigidity of the abdominal muscles is:

Harry K——, thirteen years old, admitted June 15, 1899. He had never had a similar attack. Six days ago he was struck in the abdomen with a fist. That evening he had slight general abdominal pain. The following day he vomited several times. The pain and tenderness became localized to the umbilical and right iliac regions. Cathartics were given before he entered the hospital, and the bowels moved freely. Pain and tenderness had persisted up to date. The bowels moved well on the day of admission, when he also vomited greenish fluid as he had done the day before. The tongue was moist and coated; there was slight conjunctival icterus. The abdomen was soft on the left side, but on the right side there was marked muscular rigidity. Owing to this rigidity, nothing could be felt of the appendix or its surroundings. Rectal examination was negative. On the day of admission the pulse was 118; the temperature, 102° F. On the following day, in spite of the fact that pulse and temperature both dropped to 100, I determined to open the abdomen. I was led to this conclusion solely by the persistent rigidity of the abdominal muscles on the right side. I found the appendix. with a perforation at the tip, behind the cæcum, and surrounded by an abscess cavity. The boy made a prompt recovery.

With the exception of the rigidity of the abdominal muscles, the abdominal and rectal examinations in the case were negative. But in the onset of an attack, by examining the right iliac fossa carefully, we can usually feel what we are accustomed to call a "mass." This "mass" only exceptionally means an abscess. It usually means that the appendix is inflamed, that its walls are thickened, and that there are adhesions around it. We must not be deceived by feeling the edge of the rectus muscle, or by fecal masses in the cæcum. Having made our abdominal examination as thoroughly and as gently as possible (to avoid rupturing an abscess that may be present), the next step is to examine by rectum or by vagina, and if possible by both. Too much stress cannot be laid on the value of vaginal and rectal examination in appendicitis. In women the vaginal examination is of prime importance, but even in men and children the rectal examination is often invaluable. We can often make a diagnosis from the rectal examination when the abdominal examination yields no positive result whatever. But it must be borne in mind that we are not by any means through with our examination of a case of acute appendicitis when we have examined the abdomen and the pelvis. All the organs in the body should be carefully examined. The lungs may show a beginning consolidation, and we know that in the initial stage of a pneumonia the abdominal symptoms frequently predominate. Marked enlargement of the spleen would lead us to suspect typhoid fever or malaria, both of which diseases sometimes resemble an acute attack of appendicitis. Naturally the examination of the blood and urine would be immediately made in a doubtful case. Even after we have examined all the organs in the body there are still two data that we must ascertain, one of which is of great value; I refer to the pulse and temperature. In every case of acute appendicitis there is some increase in the rapidity of the pulse, and generally also some rise in the temperature. But pulse and temperature often do not show a corresponding increase. And what is of the greatest importance, we may have but slight elevation of pulse and temperature with grave pathological changes in the appendix.

Granting that we have made the positive diagnosis of appendicitis, we are at once confronted by the momentous question: What are we going to do about it? There is a quite general unanimity of opinion among surgeons and even among medical men that almost every case should be operated upon; but when? There is the rub. Have we any sign or any symptom, or any group of signs or of symptoms by which we can judge in every case when to operate? Unfortunately, we have not. He would be a skilful diagnostician indeed who could say, "Here we have a simple catarrhal appendicitis," "Here there is a threatened perforation," "In this case there is a foreign body in the appendix," and so on. The time may come when we shall be able to describe the exact pathological process in the appendix before the operation, but to-day all our efforts must be centred on the question, Shall we operate? In deciding this question, on which in so many cases the life of the patient depends, we must take everything connected with the case into consideration. The age of the patient, the previous history, the general physical development, the history of the attack, the symptoms, and the result of the examination, all play a rôle in aiding us to arrive at a correct conclusion.

In regard to the signs and symptoms that may aid us, pain, tenderness, vomiting, tympanites, rigidity of the abdominal muscles, may all be moderate, and yet we may have a dangerous case before us. As a rule, not much importance should be attached to the temperature alone, but it should always be carefully measured, and never by mouth. I had a striking illustration of this recently at the hospital. One afternoon while I was operating, a patient was admitted with a pulse of 120 and a temperature of 98.6° F. I examined the case and found a marked rigidity of the abdominal muscles, and some tympanites. Tenderness was general, but more marked on the right side. The pulse was 120, as had been reported. The house surgeon suggested that the rapid pulse might be due to the transportation of the patient to the hospital. However, the man looked sick, and on inquiry I found that the temperature that had been reported was mouth temperature. The rectum showed 102.4° F. I operated at once and found a perforated appendix, beginning general peritonitis with considerable sero-purulent fluid in the small pelvis. The case had been treated with hypodermic injections of morphine for three days. The man's life hung on a thread for three or four days after the operation, but he finally made a complete recovery. Personally, I put more confidence in the rapidity and character of the pulse than in the temperature. The relation of pulse to temperature is sometimes of importance. A high temperature with a rapid pulse always means a severe inflammation, and with a positive diagnosis of appendicitis should generally indicate operation. Even more serious perhaps is a rapid pulse with low temperature. Such a relationship of pulse to temperature generally points to a perforation of the appendix without adhesions, and a consequent general peritonitis. The temperature is still low because the perforation is recent. If we wait, the temperature will go up—and so will our patient.

Some surgeons have tried to bind themselves to some hard-and-fast rule as to when they will advise operation, but they have few followers in this. True it is that if the pulse is 120 or more and remains so, we should operate. But it is a dangerous rule to say that we should wait until the pulse is so rapid before operating. In one of the worst cases of appendicitis with general peritonitis that I operated on, there was a pulse of only 100. We must take every factor of the case into consideration. If we have a frightened, neurotic woman before us, a pulse of 120 is not so serious as a pulse of 110 in a phlegmatic man. Then, again, the whole general condition of the patient must aid us. Is the tongue dry, is there much rigidity of the abdominal wall, is there tympanites, is the pain severe, is the tenderness marked, is the facial expression anxious? In the face of two of these signs or symptoms being marked, I would favor an early operation, even if the pulse was not very rapid, or the temperature high. The character of the pulse is a condition that is often overlooked. A small, compressible pulse, especially if it is irregular, even though it is not yet rapid, is to my mind a more grave symptom than a rapid, full, regular pulse. The anxious facial expression sometimes induces us to operate, and we generally find graver conditions than pulse and temperature would warrant us in expecting; or we may find complications that give rise to no symptoms. Not long ago I was impelled to operate on a woman in whom the symptoms were not very severe, but the facial expression was anxious. I found a moderately inflamed appendix with a tight stricture near its centre, and, to account for the anxious expression, a retroverted impacted uterus which gave rise to no symptoms, and which I was enabled (in Trendelenburg's position) to replace through the incision I had made for the removal of the appendix. The condition of the bowels does not often help us. We find diarrhœa or constipation in mild as well as in severe cases. The functions of the bladder sometimes aid us. Dysuria and painful micturition are important symptoms. I recollect a case in which these two symptoms, together with a small irregular pulse, led to an early operation, and we found an appendix advanced in disease.

Again, other surgeons have laid down the rule to operate on every case of appendicitis as soon as the diagnosis is made. This would make a malignant disease of appendicitis, which in very many cases it certainly is not. To quote from a recent paper of Richardson: "If in every case we operate as soon as the diagnosis is made, we may operate at that very time when the patient's best chance lies in conservatism."

Each case then must be carefully examined, and all the evidence we can collect must be weighed in the balance. I have laid down one little rule for myself that I believe has aided me in saving a few cases, and that is: "If in doubt, give the patient the benefit of it by operating."

How is it, then, with a case in which we have made the diagnosis of acute appendicitis, but in which the signs and symptoms are not severe enough to warrant an immediate operation? Here the problem is not so difficult. We keep the patient in bed, on a liquid diet. We give no cathartics, we give no opium, we give no morphine. Only in exceptional cases do we give enemata. We place a light ice-bag over the region of the appendix. We have a trained nurse at the bedside day and night; she counts the pulse every hour and measures the temperature regularly every three hours, and whenever there is any increased rapidity of the pulse. We examine the patient carefully three times in twenty-four hours and note the progress of the case. And just here lies the great danger in administering opium. We cannot correctly judge of the intensity of the symptoms if we deliberately mask those symptoms by giving narcotics. How can we tell if the pain has increased, after we have deadened it with opium? The same is true of the tenderness. Moreover, we are very apt to have tympanites develop if we give opium; and who can differentiate between such a tympanites and that of a beginning peritonitis? No, let us administer no opium, but rather give nature full sway and allow her, as the disease progresses, to display her various danger signals. What are these danger signals? If we find the pain and the tenderness (for these are two different things) on the increase; if we find the abdominal wall, which the day before was soft even on the right side, becoming rigid, then we advise operation, even though there has not been much change in the pulse or temperature. If at any time in the course of an attack a chill manifests itself, immediate operation is imperative. If the pulse, as the disease progresses, does not show a tendency to become slower, but rather more rapid, even though the temperature is but slightly elevated, the appendix should be removed. Persistent nausea or vomiting is generally associated with obstinate constipation, and means an involvement of the peritoneum—rarely operation is advisable, even in the presence of a slow pulse. A rapid pulse with high temperature early in the disease means pus; we should operate even though we cannot feel an abscess. There may be no abscess—the pus may be inside of the appendix (empyema). In some doubtful cases the presence of a marked leucocytosis will aid in confirming our diagnosis of pus. If we feel an abscess forming, we watch our patient very carefully and, if possible, wait a few days until firm adhesions form. We must not expect to get fluctuation, for we very rarely do. In the following case of an intelligent male nurse, I diagnosed the beginning formation of an abscess and waited for firm adhesions:

C. G——, aged forty-three years, September 23, 1899. The first attack began forty-eight hours ago with severe pain in the umbilical region, which soon became localized to the right iliac fossa. Pain and tenderness were more severe than at the outset. The patient had been nauseated since beginning of the attack, but had not vomited. The bowels were constipated; two enemata given before admission were ineffectual. The patient felt worse than at any time since the beginning of the attack. The abdomen was soft except over the right iliac fossa, where the rectus muscle was tense and rigid. Rectal examination was negative. Temperature 99.6° F.; pulse, 100.

September 24th: Temperature, 100.4° F.; pulse, 80–90.

September 25th: Temperature, 100.6°–101.2° F.; pulse, 97–92.

September 26th: Temperature, 99.8°–100° F.; pulse, 68–76.

During this time an abscess was made out, and it was decided to wait for firm adhesions to form.

October 1st: Temperature, 98.6°–99° F.; pulse, 66–72. The tenderness had subsided except over a mass the size of an orange, near the outer wall of the pelvis on the right side. I now decided to operate. I found an abscess behind the cæcum containing about 100 gm. of fetid pus. Search was then made for the appendix, which was found with some difficulty. It had sloughed away completely from the cæcum, its base being gangrenous, and was attached only by its mesenteriolum. The wall of the cæcum where the appendix had been attached was covered by a thick layer of fibrin. The tip of the appendix was tightly adherent low down in the pelvis over the iliac vessels. The perforation had taken place close to the cæcum where the appendix was gangrenous. The man made an excellent recovery.

If a large mass is felt per rectum or per vaginam, immediate operation should be insisted on. A very sad case I saw recently will prove the correctness of this statement: A boy was admitted to the hospital at 12:30 P.M. with an appendicitis of three or four days' standing. Pulse, 100; temperature, 101.2° F. On rectal examination the house surgeon felt an abscess low down in the pelvis. One of my colleagues was to operate on another case at 2 P.M., so the case was reserved for him. I examined the case shortly after two o'clock and could detect no abscess per rectum. The boy looked anxious; his pulse in two hours had jumped from 100 to 140, and when the abdomen was opened it was found full of pus—the abscess had ruptured. Had the boy been operated on two hours sooner, his life would have been saved. This case also emphasizes what was said above concerning the value of rectal examination. Without it no diagnosis of abscess could have been made, nor would it have been suspected, as the pulse was only 100 and the temperature 101.2° F.

During the time that elapses from the onset of the attack until the time of operation, too much care and attention cannot be devoted to a case of appendicitis. The responsibility that rests on the shoulders of the physician is even greater than that of the surgeon who performs the operation. For it is well known that, with modern aseptic technique, the removal of the appendix is not associated with much danger; provided, of course, the inflammation is confined to the appendix.

If, on the other hand, the signs and symptoms under rest in bed, fluid diet, and ice-bag locally, decrease, we should endeavor to tide the patient over his acute attack. What shall we do when we have tided him over the first attack? Shall we advise every person who has had one attack to have the appendix removed? Many surgeons and some physicians do so advise. Unless the attack has been a severe one, I would not, in every instance, advise the removal of the appendix after one attack. There are undoubtedly many cases of catarrhal appendicitis that, with careful regulation of diet, proper exercise, and mild saline laxatives, are for years following a first attack entirely free from symptoms. Such patients should have appropriate treatment, and should not be urged to have the appendix removed. At the same time, I believe it is but fair to warn them that they are in danger of having a second attack at any time, and that the second attack may be much more serious than the first. Such a patient, who has had one even moderately severe attack, should not travel in unfrequented places, or go to any place where he cannot have prompt surgical treatment if the emergency arises. It is for the intelligent patient to decide in such a case whether he wishes to have his appendix—his sword of Damocles—removed. And many such patients will so decide; especially as they often have uncomfortable sensations in the region of the appendix. But such patients should not be told that the interval operation is entirely free from danger. There is danger in every administration of an anæsthetic, there is danger in every operation. True it is, the risk is very small, especially when compared with the dangers of a second, more severe attack of the original disease. Should a patient have had two attacks, I would in every instance advise the removal of the appendix. In so advising, I am well aware that some persons get along very well even for years after a second attack; for I have myself seen such cases. But the danger of a third attack is too great, and it is doubtful if there is ever a restitutio ad integrum after two attacks of appendicitis. Moreover, the third attack is apt to be more severe than the previous ones; nor is any one able to say how near an appendix that has been twice inflamed is to perforating. I recently operated on a case that is to the point, and, moreover, the case proves the falsity of the ground held by some that an interval operation should be performed only if the appendix can be felt through the abdominal wall:

Dora H——, aged ten years, was admitted to Mount Sinai Hospital September 23, 1899. The patient had the first attack four months ago; the attack lasted six days. The second attack began twelve days ago with vomiting, and severe pain in the right iliac region. This attack lasted seven or eight days, and was more severe than the first. The patient entered the hospital with normal temperature and slow pulse. Nothing could be felt by abdominal examination.

September 26th: Temperature, 98.6° F.; pulse, 80. Operation: The usual incision was made and the colon readily found, but not the appendix. The hand introduced felt adhesions around the gall bladder. The incision was enlarged upward, and the gall bladder was found adherent to the transverse colon and to the small intestine, forming a densely adherent mass. In separating the colon from this mass, a very small abscess was broken into. With considerable difficulty the gall bladder, which was firmly adherent to this mass, was liberated, and the necrotic appendix was then felt to the left of the gall bladder and behind the liver. Owing to the deep location of the appendix and to the fact that pus had been formed, I did not deem it safe to attempt the removal of the appendix. It finally sloughed away completely; there was a slight fecal discharge for a time, but the recovery was ultimately complete.

This case was technically about as difficult a case of appendicitis as one could find; the separation of the adhesions was long and tedious, and had a perforation taken place during an acute attack, the finding of the appendix in such an unusual location would have been even more difficult and dangerous than it was. This case helps to clear up several moot points: (1) It is dangerous to wait for a third attack. (2) After two attacks, the appendix should be removed, even though it cannot be palpated. (3) We cannot tell by the most careful exaination how far advanced in disease an appendix is.

Nor is this case an isolated one. We frequently cut down on an appendix in the interval between attacks, and are often surprised at the amount of inflammation we find in and around the appendix, and that too in cases in which there is little or no pain, temperature and pulse are normal, and little or nothing can be felt on careful examination. I had a very striking illustration of this quite recently in the case of a patient who had had but one attack of appendicitis:

Miss C——, a native of Augusta, Ga., aged twenty-two years, was perfectly well until six months ago. She was at that time in bed for two weeks with an attack of appendicitis of moderate severity. Following the attack she suffered from loss of appetite, obstinate constipation, and various nervous symptoms, including fainting spells. As none of these phenomena had been present before her attack, and as she also had slight pain at times in the region of the appendix, and moreover as I could elicit tenderness on deep pressure in the right iliac fossa, I concluded that there was an inflammatory process going on continuously in the appendix. In spite of the fact that pulse and temperature were normal, I advised the immediate removal of the appendix. This advice resulted in the hasty summoning of the patient's parents from Georgia. Their arrival was followed by a consultation with Dr. Bull, who agreed with the diagnosis, but who did not consider the case so urgent as to prevent the patient's being taken to her home and having the appendix removed there. In this I did not concur, and the result was that the patient entered Mount Sinai Hospital, where I removed her appendix by the gridiron operation. I found an appendix three and a half inches long with a tight stricture one-quarter of an inch from its tip and another one half an inch from its base. The whole organ was moderately congested but not adherent. On cutting it open I found considerable brownish, muco-purulent material, and eight distinct coproliths. These were all situated between the two strictures. The mucous membrane was extensively ulcerated, and in places the ulceration had extended into the muscularis. An acute inflammation might very well in a few hours have brought about a perforation. And yet, in spite of the grave pathological condition that had for months been insidiously developing in the interior of this appendix, the only subjective symptoms were loss of appetite, constipation, and very slight pain at times. The only objective symptom that was present was slight tenderness on pressure over the appendix.

This case is not an isolated one. Many patients go about for months and months with such a chronic process in the appendix; then they develop an acute attack, and in a very few hours perforation has taken place. The lesson to be learned from these cases is obvious. If, after a first acute attack, the patient has pain (be it ever so slight) repeatedly in the region of the appendix, the removal of the organ should be strenuously insisted on; and that too in the absence of all other symptoms, and even in the face of an absolutely normal temperature and pulse rate.

To summarize:

I. Not every case of appendicitis should be operated on.

II. After a first mild attack, try regulation of diet and salines.

III. After a first severe attack, remove the appendix.

IV. After two or more even mild attacks, operate.

V. In an acute attack (1) do not give opium or morphine. (2) Operate during an attack, (*a*) if a chill manifests itself; (*b*) if the pain is severe enough to require morphine; (*c*) if the pulse is very small, or rapid, or irregular; (*d*) if there is persistent vomiting; (*e*) if there is persistent rigidity of the abdominal wall; (*f*) if an abscess can be felt; (*g*) if the general condition makes it imperative; (*h*) if in doubt.

But it must not be supposed that every case comes under one of these headings, although the great majority of them will be found to do so.

In conclusion, I would say that I have endeavored honestly to outline what I believe to be the best plan of treatment in the most important abdominal disease we meet with in this country. I have seen many patients get over a primary attack; I have seen many recover from a second and a third attack. I have seen cases free from attacks for years, and then succumb to a perforative attack. I am well aware of the dangers, both primary and secondary, of an operation during an attack. I have seen only too many cases operated on too late. I know there is a distinct danger in the interval operation, even though a very small one, and I recognize the fact that it should not be lightly entered upon. I do believe that if every case was operated on early, the mortality would be reduced. But I also believe that by exercising care and discrimination in our cases we can reduce the mortality just as much, perhaps more than if we operated on every case, and we shall at the same time only be operating on those cases that need an operation. The grand ideal in the management of these cases is the hearty co-operation of the physician and the surgeon, together with that *sine qua non*, an intelligent patient. Very often, when the pros and cons are laid before such a patient he will unhesitatingly decide on the proper course of action. May we not hope that in the near future physician, surgeon, and intelligent patient, working hand-in-hand, will reduce the awful mortality of this dread disease—appendicitis!

5 West Eighty-fifth Street.

1. ON A PECULIAR VARIETY OF PATHOGENIC STREPTOCOCCI. 2. ON A PECULIAR PROPERTY POSSESSED BY (AT LEAST SOME OF) THE PATHOGENIC BACTERIA: PRELIMINARY COMMUNICATION.

By E. LIBMAN, M.D.,
NEW YORK,
ASSISTANT PATHOLOGIST, MOUNT SINAI HOSPITAL.

1. This streptococcus was isolated in pure culture from the mucoid portion of the stools from a case of acute entero-colitis, in the service of Dr. Koplik. Besides differing in a number of smaller details from ordinary streptococci, it possessed a feature not before described. When grown on glucose-agar, the whole agar became whitened, although the growth was confined to the surface. The same happened with lactose-agar, but not with saccharose-agar. A very marked result was obtained by growing the organism on glucose-agar to which some hydrocele fluid had been added; the medium became absolutely white, as if it had been heated or an acid had been added.

Anaerobically, a similar result could be obtained with the serum medium only. The whitening of the media seems to depend on the production of an acid (lactic acid or one closely allied) which precipitates the albumin of the media. The organism is pathogenic for mice, causing an acute inflammation of the gastro-enteric tract.

2. While working on the streptococcus above described, I tried to find out whether other bacteria might not have a similar property. To my surprise I found that a large number of the pathogenic bacteria can precipitate serum-albumin in the presence of glucose. In a general way the result seems to depend upon the amount of acid produced. Pneumococci are the only pathogenic organisms hitherto tested which do not possess this peculiar property. Many bacteria can also precipitate egg-albumin. Most of them precipitate serum-albumin in the presence of 0.1 per cent. of glucose, the amount present in the blood normally. With lactose, maltose, and saccharose the results are not so constant.

The saprophytes (I do not include the proteus group here) which I have thus far tested do not seem to possess the same property. The growth of most of the bacteria used in the experiments, including pneumococci, on a medium consisting of glucose-agar to which some serum has been added, is far in excess of their growth on any other medium.

In my complete paper, the question will be touched upon, of what importance these facts may be in relation to infections, particularly in diabetics. Likewise the possibility of differentiation of species will be referred to.

I desire to express my obligations to Dr. Koplik for the case upon which these observations are based.

180 East Sixty-fourth Street.

Report of a Case of Gunshot Wound of the Pregnant Uterus and Fœtus; Cæsarean Section; Recovery.—H. L. Nietert reports this case of a woman nineteen years old. The patient was perfectly well when last examined, three months after the operation. The case is a very rare one, a record of only one case being found in which Cæsarean section was performed for gunshot wound of the uterus. There was no infection. The skin about the bullet wound contained a large powder burn, at one side and just below the hole, giving indications that the weapon had been held near the body and that the wound had been self-inflicted. The direction the bullet had taken also pointed to this fact. The patient finally admitted this to be true.—*Medical Review*, April 21, 1900.

A Fatal Case of Congenital Bullous Eruption in an Infant.—R. H. Kennam says that bullous eruptions in the infant occur in two classes. One is pemphigus neonatorum. Descriptions of several cases of this form are epitomized by the author. The other class is the pemphigoid eruption of hereditary syphilis. The contents of the bullæ tend to become sanguineous, the differential diagnosis from the first class being made by observing the nature, time of appearance, and position of the bullæ, and the associated cachexia. He finds it difficult to bring his own case under either of these typical categories, though he does not doubt that it belongs to one of them. In this special case the bullæ appeared on the third day of life, the child dying five days later. Extended reference is made to the literature of the subject.—*Dublin Journal of Medical Sciences*, April, 1900.

The Diagnosis of Rabies.—G. Daddi says that the best method for ascertaining in a short time (twenty-four to thirty-six hours) whether a suspected animal was mad or not, is to make a histological examination of sections of the brain, cerebellum, spinal marrow, and intervertebral ganglia. The alterations in hydrophobia will consist in destruction of cells, atrophy or swelling, chromatolysis or vesicular deformation of the cells, homogeneous swelling and vacuolization of the protoplasm, granular-fatty or pigmentary degeneration, or swelling of the protoplasmic and nerve prolongations, disappearance of these prolongations and of the nucleus. A special alteration of the nerve ganglia consists in a destruction of the nerve cells and neoformation of the endothelial cells of the spaces in which the ganglia are situated. Negative results are more valuable than the positive ones obtained. A normal nervous system cannot belong to a rabid animal.—*Rivista critica di Clinica Medica*, April 7, 1900.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifteenth Annual Meeting, held at Washington, D. C., May 1, 2, and 3, 1900.

EDWARD G. JANEWAY, M.D., OF NEW YORK, PRESIDENT.

Third Day—Thursday, May 3d.

Case of Filaria with Specimens of the Adult Parasite.—DR. W. T. COUNCILMAN, of Boston, read this paper. The patient was a native of Barbadoes, and had had the disease for five years. It was interesting to note that in this case chyluria was absent.

The Elimination of Deleterious Substances from Antitoxic Sera.—DR. WILLIAM H. PARK, of the board of health of New York City, read this paper. He said that antitoxins were of the nature of globulins, and at first it had been hoped to separate the toxins from other globulins in the blood that produced the rashes, but this effort had been unsuccessful. Filtering the serum had no effect in preventing rashes following their injection. The sera of different horses differed markedly so far as irritating symptoms were concerned. The sera of some horses were far less harmful than others. He thought the only way left was to select those horses whose sera were non-irritating. With an increased amount of toxins in the blood serum there was also an increase in the globulins.

DR. GEORGE PEABODY, of New York, asked if any decision had been arrived at relating to the idiosyncrasy of the toxin, *i.e.*, after a patient had once been injected with the toxins and a rash followed, would the rash appear after the second injection?

DR. PARK said that he had had only one such case, and in that a second rash had occurred.

Varieties of the Diphtheria Bacillus.—DR. F. F. WESTBROOK, with DRS. WILSON and MCDANIEL, of the Minneapolis board of health, read this paper. He abandoned the old classification of true and pseudo forms, and divided the bacilli into three groups, viz., (1) granular forms, which were metachromatic, there being seven kinds, numbered by letters from a to g; (2) barrel forms, numbered from a^1 to e^1; and (3) solid color forms, numbered from a^2 to g^2.

DR. A. C. ABBOTT, of Philadelphia, said that we did know the normal diphtheria bacillus—in fact, it was questioned if it was a bacillus. He thought that many of these forms would change by some slight alteration in the culture medium.

DR. PARK said that there was no way of telling the virulence of the organism under the microscope. Some of the forms described by Dr. Westbrook were considered in New York to be streptococci and not diphtheria bacilli.

DR. WESTBROOK said that one would be inclined to agree with Dr. Park, but for the fact that when cultures of those forms resembling streptococci were injected into a guinea-pig, death was produced, and after death the cultures showed a change in form of the organism.

Presentation of a Case of Addison's Disease under Treatment with Suprarenal Extract.—DR. W. W. JOHNSTON, of Washington, D. C., presented this case, and said that the points of interest were the acute development of the disease, together with the very rapid improvement, as shown by gain in weight, under treatment with suprarenal extract.

Venous Thombosis as a Complication of Cardiac Disease.—DR. WILLIAM H. WELCH, of Baltimore, read this paper and reported four cases that had been under his supervision. He then reviewed the literature of twenty-three cases. The first of his own cases was the most interesting. The patient was a negress, seventeen years old, who had entered the hospital with signs of mitral disease. The right arm became painful and swollen, and a diagnosis of thrombus was made. The patient died, and the autopsy showed complete occlusion of the axillary, innominate, and jugular veins. Cultures taken from different parts of the body were sterile, except those from the thrombus.

DRS. F. P. KINNICUTT and HERMANN BRIGGS, both of New York, each recalled a case.

The Nature of the New Tissue in Cirrhosis of the Liver and its Distribution.—DR. SIMON FLEXNER, of Philadelphia, read this paper. The new liver tissue was made up, he said, of elastic tissue and white fibrous tissue. The pathology was not well understood. By staining and by digesting out the fibrous tissue, the elastic tissue would be left. In this way it was possible to demonstrate what part of the new tissue was made up of one or the other forms of the connective tissues.

Cystoma of the Pancreas.—DR. R. H. FITZ, of Boston, read this paper. The case was a multilocular cyst of the pancreas, which had been removed by an operation. The patient was still living.

Degenerated Echinococcus Cysts of the Pleura.—DR. CHARLES CARY, of Buffalo, reported this case, and said that the interesting point relating to it was that the patient had never been out of the United States. The specimen was on exhibition.

Aneurism of the Aorta with Rupture into the Superior Vena Cava, Recognized during Life.—DR. ALFRED STENGEL, of Philadelphia, read this paper and reported a case. He thought that it was not only useless to do a venous section in such cases, but that it was absolutely dangerous.

Minor Forms of Cardiac Dilatation.—DR. BEVERLEY ROBINSON, of New York, read this paper. He thought that this condition was frequently mistaken for other ailments. There were several types in which this condition occurred. The first was the anæmic girl who had just passed the age of puberty. The disease might lead to organic change, but generally the cases were self-limited. The next was the obese woman between forty and fifty years of age. He said that such women often had a soft systolic murmur at the apex. The next type was that of the thin, nervous woman of about the same age. Dr. Robinson said that laboring men might not suffer from any valvular disease, but still might have some dilatation. As to treatment, he would say that even young girls did well on digitalis and stomachics.

Graves' Disease without Exophthalmic Goitre.—DR. W. H. THOMSON, of New York, read this paper. He thought that there were other symptoms besides the enlarged thyroid gland and exophthalmus by which one could make a diagnosis of Graves' disease. The most important symptom, and the one that was generally first to appear, was tachycardia. The nervous symptoms were the next in importance, and these might be either sensory or motor disturbances. Among them were pains in the eyes, colored spectra, tinnitus, insomnia, and fear, more marked in the morning than during the night. Oftentimes the patient would have shifting pains in the extremities. Dr. Thomson spoke of the weakness and tremor of the voice in these cases. The gastric symptoms were very important. There was persistent vomiting, with anorexia, nausea, and diarrhœa, which was not accompanied by pain. There was no mucus in the stools and no odor to the fæces. Loss of the hair was often characteristic. Tremor of the eyelids was the most constant symptom. Death generally took place by syncope. He thought diet had a marked effect in causing the disease, and consequently that the disease had its origin in the gastro-intestinal tract.

Perichondritis of the Larynx in Typhoid Fever, with Exhibition of a Patient and a Specimen.—Dr. M. H. Fussell, of Philadelphia, read this paper and exhibited a patient who had had the disease. It was necessary to perform a tracheotomy, and the patient recovered. The tube was taken out later, and the patient was able to speak very distinctly.

The Attitude of the Physician and Surgeon to Appendicular Symptoms Complicating Typhoid Fever.—This paper was read by Dr. H. A. Hare, of Philadelphia. He spoke of the difficulty in making a diagnosis in the early stage of typhoid fever, and said that he had seen cases in consultation that simulated appendicitis, but in twenty-four hours a typical typhoid fever had been present. He thought these cases might be explained by the fact that there really was an appendicular inflammation present, or that there was a marked ulceration in the neighborhood of the appendix.

Observations on Appendicitis.—Dr. Ira Van Gieson, of New York, read this paper. He thought that the appendix was predisposed to septic attacks because of its development, and that the attacks were due merely to mechanical interference. Acute appendicitis was not due to an accident, but was the result of a process of natural selection. He said if the appendix was removed at birth, or a short time after, the operation would interfere with that of natural selection. He spoke of the exciting causes of appendicitis as being of a bacterial origin, and mentioned the streptococcus, bacillus coli, and pneumococcus as being the most common ones.

Some Observations on Human Temperature in Disease.—This paper was read by Dr. Norman Bridge, of Los Angeles.

Study of a Mummy Affected with Infantile Paralysis.—Dr. J. K. Mitchell, of Philadelphia, read this very interesting paper. The subject was that of an Egyptian mummy, which had been embalmed about 3700 B.C. That he was an old man was shown by the worn molars, and the condition of the costal cartilages. The left leg was a little shorter than the right. There was no evidence of fracture, but there was a thickening of the femur on the left side. Dr. Mitchell said the pelvis was perfectly formed and there was no diseased condition of the vertebra. No curvature of the spine was present. These facts seemed to show that the subject walked with a high shoe made to counteract the shortening, and that the case was one of anterior poliomyelitis.

A New Modified Sphygmograph.—Dr. Robert T. Edes, of Jamaica Plain, Mass., read this paper. He paid special attention to the arterial tension.

The following papers were read by title: "The Existence of Bacteria in Normal Tissues," by Dr. G. J. Adami, for Dr. W. Ford, of Montreal: "Sub-Pectoral Abscess," by Dr. J. H. Musser, of Philadelphia; "Stone in the Kidney and Conditions Stimulating It," by Dr. D. D. Stewart, of Philadelphia; "The Circular Fibres of the Heart (Mitral Sphincter) as a Factor in Functional Disturbances of the Heart with Mitral Insufficiency," by Dr. Morton Prince, of Boston; "Graves' Disease without Exophthalmic Goitre," by Dr. D. D. Stewart, of Philadelphia: "Would It Not Be a Gain to Both Pathology and Practice if a Direct Interaction between the Morbific Agent (Noxa) and the Reparative Effect were Recognized and the Conception of an Intermediate, so-called Inflammatory Process Abandoned?" by Dr. Andrew H. Smith, of New York; "The History of a Case of Circumscribed Scleroderma," by Dr. S. B. Ward, of Albany; "Clinical Types of Uric-Acid Diathesis," by Dr. J. N. Danforth, of Chicago; "Sarcoma of the Stomach," by Dr. George Dock, of Ann Arbor; "A Case of Multiple Fibromas of the Nerves with Arthritis Deformans," by Drs. L. Hektoen and R. B. Preble, of Chicago; "Multiple Myeloma," by Dr. J. H. Wright, of Boston; "The Urea Content of the Blood in Cases of Nephritis," by Dr. J. S. Thacher, of New York; "A Study of Twenty-Four Cases of Typhoid Fever with Symptoms of Peritoneal Infection—Laparotomy," by Dr. George B. Shattuck, of Boston, for Drs. George B. Shattuck, J. Collins Warren, and Farrar Cobb.

AMERICAN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2d.

Benign Obstruction of the Pylorus.—Dr. Frederick Kammerer, of New York, read this paper. He divided the subject into two heads, congenital and acquired. Under the first he considered the acute form, absolute at birth, and congenital hypertrophy of the pylorus. Among the most important of the acquired forms were fibrous stenosis, benign tumors, syphilitic gummata, gall stones obstructing the pylorus, and spastic contractions of the pylorus associated with hyperchlorhydria. In regard to the treatment he emphasized the necessity of dietetics and of faithful lavage. These failing, surgical measures should be resorted to, dilatation, even up to 40 French, via the mouth, having been shown to be not only dangerous but ineffectual. The mortality from this treatment was about twenty-seven per cent. Of the operative procedures, he spoke first of resection of the pylorus; second, of Loreta's operation; third, of division of the pyloric adhesions. He said that total pyloric resection for benign tumors had been abandoned. Divulsion was also passing into disuse because of recurrence, though it was still used by the English, who obtained good results in cases of hyperchlorhydria associated with spasm. Adhesions might be the sole cause of obstruction, and might be entirely relieved by breaking down; but these cases were rare. He described one of his own. The speaker then made a comparison of the two procedures, pyloroplasty and gastro-enterostomy. The technique of the last had so improved that the mortality (fifteen per cent.) was evenly divided, as was shown by recent German statistics. Pyloroplasty was contraindicated by dense adhesions, but this was not so of gastro-enterostomy, which was here the operation of choice. As to the technique of the operations, he said that posterior gastro-enterostomy was unquestionably the better. The anterior union was almost always complicated by a spur, as well as by serious vomiting. He emphasized the advantages of Murphy's button over the purse-string suture, agreeing in this respect with Czerny, and stated that in placing the button the constriction must be made very tight. Another advantage of the posterior operation was that complications arising from the immediate pressure of the jejunum and colon were not possible. In regard to the immediate and remote results of these two operations he pointed out that with the contraction of a dilated stomach, after gastro-enterostomy the opening was almost certain to contract, particularly if the purse-string method had been used. He spoke of biliary regurgitation in this operation, and of vomiting, and stated that entero-anastomosis often counteracted these and other untoward symptoms. The speaker advised pyloroplasty when the pylorus was not seriously involved, because of the absence of post-operative complications. On the other hand, this operation was uncertain, particularly in cases of motor insufficiency. In such a condition, particularly with adhesions, posterior gastro-enterostomy, by means of the Murphy button, was the operation of choice.

Gastric Dilatation; Gastroptosis.—Dr. B. F. Curtis, of New York, read this paper. He began by outlining the normal position of the stomach. If the pylorus and lesser curvature were palpable, this one sign was enough to diagnose disease, for they were normally far beyond reach. Gastrectasia was more than a simple enlargement. It involved, just as in kindred conditions of the heart, dilatation and motor insufficiency. This insufficiency was relative, in proportion between the pyloric diameter and the stomach walls. The condition was very rare, except as associated with malignant disease, benign pyloric stenosis, or gastroptosis causing obstruction at the pylorus. Referring incidentally to acute dilatation, he said that the etiology was practically unknown. Brown, in *The Lancet*, reported a case of a man aged fifty-five years, who was seized with intense pain, thirst, suppression of urine, vomiting, dyspnœa, dizziness, pulse of 40, and collapse—evidence of epigastric tumor. Operation revealed a cyst, supposedly pancreatic, which yielded three pints of green fluid. The autopsy, five hours later, showed this cyst to be an enormously dilated stomach. It was interesting to note that this acute form might possibly be due to trauma of the vagi, for, experimentally, section of these nerves resulted in uræmia and gastric disturbances. Speaking of the symptoms of gastroptosis, he pointed out that it was invariably associated with the downward displacement of at least one other organ, and very frequently with a general enteroptosis. As to surgical treatment of gastroptosis, operation was indicated when medicine failed. The results of gastro-plication were good, if, at the same time that the stomach was given support, the neighboring displaced organs were put into their normal positions. Particularly was this true in women, who were peculiarly subject to gastroptosis; in these cases the ligaments of the genitalia should be shortened. In order that there might not be a disassociation of terms, Dr. Curtis said he preferred to use the term gastrorrhaphy for this operation. As to the pathology of gastroptosis one of several conditions might be found, viz.: (1) The cardia was invariably fixed. (2) The lesser curvature might be vertical. (3) There might be descent of the centre of the organ, the pylorus and cardia being fixed. As to symptoms, there was almost always a progressive emaciation, along with the usual clinical evidence of dilatation. Concluding, he said that since Treves' first operation, in 1895, a number of cases had been reported, with good results; that the outlook was bright for gastrorrhaphy, provided the accompanying enteroptosis was coincidentally corrected.

Hour-glass Contraction of Stomach.—Dr. F. S. Watson, of Boston, read this paper. He spoke shortly of the different forms of hour-glass contraction and of the functional and pathological changes associated with them; also of the symptoms and the diagnosis. Referring to the operation, gastro-anastomosis, for the relief of this condition, he gave a summary of cases, of which there had been thirty-five reported. As to the technique, he spoke of the great influence which the character of the contraction had on the type of operation, and mentioned the German method, which amounted to a lateral anastomosis of the two bulbs. The speaker then drew attention to an operation he had devised for the relief of this condition. It consisted in opening the lesser bulb, washing it free of stomach contents, superimposing it on the greater, cutting the apposed walls with one stroke of the knife, and suturing these; finally, suturing the first wound and closing the abdomen. In one case the patient was well on the twenty-first day. A second case he found complicated by very dense adhesions, and autopsy revealed an undiscovered perforating ulcer at the isthmus of the bulbs. He concluded by saying that his operation offered the following advantages over lateral anastomosis: (1) It avoided the great blood-vessels. (2) It avoided the stomach contents. (3) The opening was large and free. He added that gastro-enterostomy was contraindicated in cases of hour-glass contraction, because it lost to the patient the very valuable pyloric mucosa.

Diagnosis of Cancer of Stomach.—Dr. John C. Hemmeter, of Baltimore, spoke on this subject. He said that it seemed reasonable that an early diagnosis was extremely difficult to reach, chiefly because, as yet, we knew nothing of the causative factor in neoplastic growth. In ninety-nine per cent. of cases of cancer of the stomach which had been operated on the patients died of recurrence. In the one per cent. saved, an early diagnosis was made, that is to say, the cancer was discovered before subjective symptoms of gastric neoplasm had become evident. Czerny, Rindfleisch, and Kraske opposed operating after the development of these characteristic symptoms. Of the means at hand to assist in early diagnosis, he mentioned chemical, microscopical, and physical examination. The subjective symptoms were of little value, for reasons stated. Age, likewise, was no longer thought to be of value. There was undoubtedly a period of three months—the incipient stage of the cancer—which was usually diagnosed as nervous dyspepsia or as chronic gastritis. These were very vital moments. If the case refused to yield to good medical treatment, despite the absence of any subjective carcinomatous symptoms, recourse should early be had to the clinical tests. These he considered as follows: Absence of hydrochloric acid was valuable; but in those neoplasms derived from ulceration it was very generally present. Lactic acid was simply a sign of stagnation, and was due to carbohydrate fermentation. Although it was found in eighty-four per cent. of the cases, it was obviously of little value, for no stagnation could occur till the growth was too far advanced for operation. The Oppler-Boas bacillus was present in fifty-three per cent. of the cases. It was about as valuable as lactic acid due to stagnation. In regard to tumors, three-quarters of them were not palpable. The *x*-ray test was futile. As to the gastroscope, German reports gave little hope. It was extremely dangerous to use. Gastric curettage was the very latest method of procedure. It was practised with a weighted soft-rubber tube, run in and out. There was no hope of seeing carcinomatous architecture, but the cell nuclei revealed certain changes now thought to be constant and characteristic. Mitosis was found to be irregular, one important feature being that the chromozones were not equally divided between the poles. If found, this was extremely suggestive. He said that the future treatment of gastric carcinoma would not be surgical; when the knowledge of carcinoma advanced, it would be along the lines of the biology and chemistry of the neoplastic cells, and, ultimately, surgery would be discarded for a more scientific mode of treatment.

Adhesions of the Stomach.—Dr. A. T. Cabot, of Boston, spoke on this subject. He said that adhesions were particularly prone to involve the stomach, because of the nearness of organs, themselves peculiarly liable to inflammatory change. Of the symptoms, there were two types—first, those which closely resembled biliary colic, and, second, those in which the attacks simulated chronic dyspepsia. Pain was marked in all cases, often lancinating, and might girdle or shoot down the right shoulder. Recognition in mild cases was as yet impossible; severe cases were usually operated on for gall stone. Efforts should be made to diagnose the mild cases, as they often led to a destruction of the patient's physical power and were almost always accompanied by nervous hyperæsthesia. He cited a case which came to operation after fifteen years of medical treatment; a slight kink being removed, complete cure resulted. He closed by advising an exploratory laparotomy in such prolonged cases.

Stricture of the Œsophagus following Typhoid Fever; Gastrostomy.—DR. FREDERIC S. DENNIS, of New York, presented a case of gastrostomy, on which he had operated two years ago. The cardial stenosis was a sequel of typhoid, and prior to operation no food had passed the man's mouth for three months. His condition was deplorable. He now weighed one hundred and eighty pounds. He fed himself with comfort; had no excoriations or pain at the opening, and was able to do his daily heavy work. This case was illustrative of the value of gastrostomy.

Cases of Gastro-Enterostomy.—DR. FISHER, of New York presented an analysis of several cases of gastro-enterostomy in which Dr. R. F. Weir had operated. In order to make such an analysis, it was necessary to watch the cases for years prior to operation, and for as long after the intervention. Watching consisted in making frequent analysis of the gastric contents for hyperacidity, together with observations on dilatation. He found that in cases of hyperacidity with dilatation there was a gradual increase of these objective symptoms, together with the usual subjective ones, until operation. After intervention in nearly all cases the hyperacidity was reduced, and the dilatation also. Coincidently, the subjective symptoms were permanently relieved. In regard to the lasting effect of operation on the objective symptoms, it was probable that the dilatation was much reduced, or entirely negatived, except in cases far advanced, while the hyperacidity was but changed from a constant to an intermittent condition.

Hip Dislocations.—DR. OSCAR H. ALLIS, of Philadelphia, spoke (by request) on various hip dislocations, and demonstrated the mechanism of displacement on the cadaver. Making fast the pelvis to a table specially constructed for this purpose, he produced, by manual effort, and without section of capsule or tendons, inward and outward dislocations of the hip. He spoke of the danger of involving the sciatic nerve in reducing by Bigelow's method of circumduction, and mentioned that his method was free from this objection. He then showed an upward dislocation and demonstrated an outward displacement, associated with fracture of the shaft, just below the trochanter. The principle of reduction was the same in every case: the head of the bone was lifted to a position opposite the acetabulum, and was supported there by an assistant, and the thigh was wrung in such manner as to allow the hand to be used as a fulcrum. In closing, he said that he wished to be remembered as having taught that no hip reduction should be attempted until the pelvis was absolutely immobilized. Under such conditions, and with the exploited technique, almost any form could be successfully reduced.

Third Day—Thursday, May 3d.

Surgery of the Stomach.—The discussion of this subject was opened by DR. W. W. KEEN, of Philadelphia. He divided the subject into two classes: (1) treatment of general stomach disease; (2) treatment of malignant stomach disease. The latter he considered by far the most important, and confined his attention to it. Prior to operating on these cases, the surgeon met two kinds of medical men: the family physician and the gastric specialist. The first was too often baneful; the second was of the utmost use. He was of use because through him alone could the surgeon reach a diagnosis early enough to hope for success. The speaker dwelt on the grave importance of the first two or three months, and urged that if so much as a possibility existed of neoplasm, exploratory incision should early be made. A palpable tumor contraindicated operation. He closed by saying that success in the future depended on early operation.

DR. M. H. RICHARDSON, of Boston, said that he wished to be put on record as opposing indiscriminate explorations. They were attended with a certain degree of danger. He felt that exploration was warranted only in cases of gastric hemorrhage which would not yield to medical treatment—in cases of gastric perforation—but urged the danger of laparotomy and the need of conservatism. He could add nothing to what Dr. Mayo and others had already said on carcinoma. With the very valuable assistance of the gastric specialists, whose skill in early diagnosis surgeons can never hope to equal, he felt that more lives would be saved by early operation in the future than were now lost through delay. As to the view taken by Dr. Curtis on the position of the normal stomach, he said he had been surprised to find in how many cases of apparent perfect health the greater curvature reached below the umbilicus. Nor did he agree with Dr. Curtis in the extreme rareness of acute dilatation. He expressed surprise at the statistics of Dr. Hemmeter as to recurrence in gastric neoplasm (ninety-nine per cent.), and said that it seemed to him high, though all his own patients had died. Finally, he said that by early operating we should get in the future as good results in gastric neoplasms as in breast and other superficial forms.

DR. MCGRAW said that he wished to show a method applicable to general intestinal anastomosis, but particularly useful in gastro-enterostomy. It was the elastic ligature. He first used this in 1891, with good results, but the Murphy button, coming in just at that moment, caused him to discard the elastic for the metal connection. He now felt that this was a mistake. A small, round darning-needle was threaded with an elastic band, which was of greater diameter than the needle (2–3). The rubber knot he tied with a bit of thread. These ligatures cut through in about three days. There could be no leakage, because of occlusion of the needle wound. He closed by saying that elastic ligature was the safest, the quickest, and best method of doing gastro-enterostomy.

DR. MIXTER, of Boston, spoke of the case of acute gastric dilatation to which Dr. Richardson had referred. The tumor was very large: it reached from the pelvis to the ribs. A singular factor was the utter impossibility of passing a stomach tube. Autopsy showed a kinked œsophagus. The fatal result was due to making the anastomosis of the stomach to the ileum. He therefore urged the need of care in tracing the duodenum to the jejunum, and there joining to the stomach.

DR. ALLEN said that in the West there were two kinds of gastric specialists, medical and surgical. He agreed with Dr. Richardson in that exploration was attended with risk, and cited a case to substantiate this view.

DR. RANSOHOFF, of Cincinnati, emphasized the point that there should be two steps in the more complex gastric operations. This was particularly true of pylorectomy, in which gastro-enterostomy should precede by perhaps two weeks. This was of value locally and constitutionally. He noted that the posterior operation seemed to him difficult, as the posterior wall was hard of access.

DR. C. B. NANCREDE, of Ann Arbor, spoke most interestingly on the evil influence of morphine used in post-operative work. In those anastomoses followed by peritonitis, the colon bacillus was constantly the exciting cause. Experimentally, some animals which were normally immune to this germ died from septic infection by it if morphine was given. In the absence of exact statistics, he felt that in man one-tenth the fatal dose of bacillus coli communis would kill if morphine was used. As to the percentage of mortality (ninety-nine) mentioned by Dr. Hemmeter, he felt that it was too high. If it was true, the surgeon had absolutely no right to do anything more radical than gastro-enterostomy.

Dr. J. E. Moore said that surgery must depend on medicine for diagnosis. All the means for early diagnosis should be exhausted; this takes but a week. Then laparotomy should be done. He cited a case of a man aged forty-two years, sick for only three weeks. There was no vomiting. The only symptoms were emaciation and absence of hydrochloric acid. He had pain for ten days only. Operation revealed an inoperable carcinoma. In closing, he touched on the importance of examining the upper end of the duodenum in cases in which the bleeding point could not be found in the stomach.

Dr. S. H. Weeks, of Portland, Me., continued the discussion by speaking on the importance of recognizing that surgical intervention could, at best, be but palliative now; and he strongly advocated gastro-enterostomy. He emphasized the use of catgut in all buried work. It could be made absolutely sterile by boiling in juniper oil. He criticised Dr. Watson's technique in gastro-anastomosis, saying that he felt the advantages claimed for it were more than counterbalanced by the additional cut, and advised the ordinary lateral anastomosis.

Dr. L. C. Tiffany, of Baltimore, urged the necessity of early diagnosis. He had seen but one case (at autopsy) favorable to operation, but recognized that if all cases of dyspepsia were treated as had been recommended, very many needless operations would be done. He considered the operation for the relief of gastric neoplasm still in its infancy, and felt that, before we could hope to know much about the condition, hundreds of cases must be diagnosed by operation, just as was done, first, in ovarian disease; second, in appendicitis. We must see the diseased stomach a vast number of times; then only should we learn.

Dr. F. B. Harrington, of Boston, said that pyloroplasty was not a desirable operation for the help of immediate conditions.

Dr. Robert F. Weir, of New York, said that in these gastric cases operation was done to meet one of four conditions: pain, hemorrhage, gastric dilatation, and delayed food expulsion. As to technique and choice of operation, he was much disposed to favor gastro-enterostomy combined with entero-anastomosis, because this did away with all untoward symptoms better than anything else he had tried. His last eleven cases had been successful. He referred to Dr. Cabot's remarks on adhesions, and cited a very complicated case of his own in which the pylorus had been kinked by bands, the relief of which proved a very important factor in the operation. He spoke in favor of the Murphy button, saying that the cicatrices which had made Senn's and Abbe's operations obsolete did not develop after its use. He strongly deprecated the employment of any technique the chief recommendation of which was a reduction in the time of operating; speed was of but little value. In closing, he drew attention to the importance of using cocaine in abdominal work.

Dr. Rodman asked that the section might hear from Dr. Armstrong, of Montreal.

Dr. Armstrong, in speaking of hemorrhage from the stomach, divided it into two classes—first, that in which the blood came from capillaries and small veins; second, that in which it came from the great vessels. In this class medical treatment did no good, and operation was indicated if the hemorrhage recurred within seventy-two hours. The first hemorrhage was rarely fatal. He spoke of the necessity of a broad opening in the anterior gastric wall, and cited a successful operation for gastroptosis. He closed by indorsing pyloroplasty.

Dr. L. M. Tiffany, of Baltimore, gave an important aid in searching for the bleeding point. It was to insert the hand and turn the stomach wrong side out.

Here the discussion was closed, and the first volunteer paper was read.

The Methods of Closing Abdominal Incisions.—Dr. M. H. Richardson, of Boston, read this paper. He placed immediate emphasis on the great advantages of the through-and-through suture over suture *en étage*, claiming, first, that it left no blind spaces; second, that it was very quickly done. The materials he indorsed were silk, silver wire, and silkworm gut. Of two thousand cœliotomies at the Massachusetts General Hospital which were sutured through and through, and which healed by primary union, but twelve returned with recurrence. Buried sutures should be non-absorbable, for they should add strength to the tissues in which they lie, and silk was to be preferred. In closing, he emphasized the point that accurate approximation of the abdominal layers was not necessary for strong union.

Dr. J. B. Deaver, of Philadelphia, agreed heartily with Dr. Richardson, and emphasized the need of carefully dressing the wound.

Dr. Weir said that in New York suturing by layer was widely in vogue. He spoke of the need of leaving the sutures loose; constriction formed a slough, which gave a nidus for the skin germs which might be found in every wound.

Dr. Fowler, of Brooklyn, showed a multiple figure-of-eight suture, which, starting within, obviated the "dead spaces" and seemed to combine the best features of both types of sutures.

Dr. Freeman, of Denver, objected to unabsorbable materials on the ground that, if left in place, they could do no good after a few days.

Dr. Coley, of New York, indorsed Dr. Weir's position; he claimed that catgut could be absolutely sterilized, and stated that while prior to the use of rubber gloves there had been six per cent. of infection in hernia cases at the Hospital for the Relief of the Ruptured and Crippled, since their introduction there had been but one infection in the last one hundred and fifty cases. Catgut had been used in all.

Dr. Mixter, of Boston, spoke of the importance of the suturing technique, laying stress on two points—to cut through muscle, and not to tie the sutures too tight.

Dr. George B. Johnson, of Washington, said he had used all kinds. He had used the method advised by Dr. Richardson till a few years ago; now he was returning to the through-and-through method, feeling that it was the best.

Dr. Nancrede said that catgut could be made sterile. He did not think that non-absorbable materials gave added strength.

Dr. Carson, of St. Louis, had used Dr. Fowler's cross-suture, and liked it. In a series of experiments not yet complete a bit of skin was removed from the wound, and this, together with an end of the catgut suture, was cultured. The staphylococcus albus (from the skin) was invariably the only germ found, and that with considerable constancy. The gut was sterile.

Dr. Ransohoff showed a purse-string suture of the peritoneum, which seemed of great value in preventing adhesions, and advised a continuous suture for the other layers. Thus he would avoid horizontal scars.

Dr. Fowler agreed that the purse-string suture reduced the danger of peritoneal adhesions.

Dr. Richardson, in closing, said that he objected to catgut more because of the difficulty in tying it than because he feared it would infect. He referred to the extremely low percentage of hernia in his records, and spoke of the good effects of gloves and mask. He ended by urging the use of the through-and-through method.

Strangulated Hernia through a Traumatic Rupture of the Diaphragm; Laparotomy; Recovery.—This paper was read by Dr. E. W. Walker, of Cincinnati. He spoke first of the extreme rarity of these cases. In his case there was a severe trauma, the injury being received in the small of the back. When the patient was seen by him, twenty hours later, his condition was very desperate. Shock was well advanced; dyspnœa was marked; there was excruciating pain over the left breast, and cough with bloody expectoration. Flatus was present, and tympany over the left lung. The heart was pushed two inches toward the right. The seventh and eighth right ribs were fractured. Median incision revealed a great rent in the diaphragm through which a large mass of bowel had slipped into the chest cavity. With great difficulty this coil, eight inches long, was withdrawn. The opening admitted three fingers. Closure was very difficult, and before it was accomplished the patient grew too weak for it to be continued. It was accordingly left unfinished, and the operation was concluded. As to technique, it was of great interest to consider the choice between the abdominal and the trans-pleural paths. He preferred the abdominal incision.

Dr. S. J. Mixter showed specimens of his case which was of great interest, because of its having resulted from muscular exertion. He found a gangrenous mass, and the gut burst during efforts at reduction.

Dr. Freeman, of Denver, advocated the trans-pleural route because of its greater ease.

Dr. R. Matás, of New Orleans, said that the trans-pleural route should always be used if a possibility of strangulation existed. It was less dangerous than the abdominal, and was preferred by Italian surgeons.

A Case of Sub-Pubic Hernia through the Pelvic Floor; Operation.—Dr. F. B. Harrington, of Boston, read this paper. He spoke of the varieties of vesical hernia, citing some of the causes. His case was that of a woman aged forty-six years. The symptoms came on very suddenly, the gravest being acute retention. When he saw her, she had a tumor eighteen by eight and one-half inches protruding from the pelvic floor. Two years before she had been operated on for fibroid of the left labium majus. Undoubtedly the present tumor had some relation with a recurrence of this condition. A vesical sound showed the tumor mass to be largely composed of bladder, but every attempt at reduction failed. After laparotomy, however, this was easy. The ovaries and tubes were removed and the uterine fundus was brought down to cover the rent in the pelvic wall after reduction. This treatment proved in every respect successful.

A Case of Acute Tuberculosis of the Mesenteric Glands of the Ileo-Cæcal Coil; Removal; Permanent Recovery.—This paper was read by Dr. M. H. Richardson, of Boston. He urged the necessity of dissecting diseased mesenteric glands, saying that it seemed as important here as in the neck. The condition was a common one; the glands were often cheesy or calcified. He suggested the possibility of a relationship between such glands and appendicitis. To show how readily such acute adenitis might be confused with appendicitis, he cited a case which presented the classical symptoms of appendicitis, but in which the appendix was normal. A great mass of glands was found and removed. The operation was a permanent success.

Dr. Allen, of Cleveland, recalled a similar case.

Apropos of the relationship which Dr. Richardson had said might exist between appendicitis and tuberculous glands, Dr. Nancrede said that he had been vainly seeking for many years a tuberculous appendix.

In the absence of Dr. J. W. Elliott, of Boston, his paper on "Successful Removal of Acutely Inflamed Tuberculous Mesenteric Glands" was read by title.

The society then went into executive session.

Afternoon Session.

In the absence of Dr. De Forrest Willard, of Philadelphia, his paper on "Congenital Cystic Tumor of the Pelvis" was read by title.

Extirpation of a Very Large Aneurism of the Renal Artery.—Dr. W. W. Keen, of Philadelphia, read this paper. Reviewing the history of this condition, Dr. Keen said that there had been reported but twelve cases. Three only had been operated upon—the first by Albert, of Vienna; the second by Hahn, of Berlin, in 1893; the third having been Dr. Keen's case. The patient was a woman aged forty-five years. She had had pain over the gall bladder for four years, with swelling on the right side of the abdomen. A vertical incision was made through the right rectus, and immediately the tumor sprang up to view. He was uncertain of its character till after its removal, when it was split; this showed it to be an aneurism. Dr. Keen spoke of the differential diagnosis; also of the fact that, presumably because of the small size of the renal artery in proportion to the size of the aneurism, pulsation was absent. The tumor was large, 14.5 cm. in diameter; it weighed 970 gm. In conclusion, he spoke of the encouraging outlook in this class of cases. Of the three patients operated on, three lived.

A paper on "Carcinoma of the Rectum," by Dr. John B. Deaver, of Philadelphia, was read by title.

Spontaneous Disappearance of Carcinoma of the Lip; Union following Pathological Fracture of the Femur due to Secondary Carcinoma.—Dr. Leonard Freeman, of Denver, read this paper. He described a case having had the characteristic reforming crust, which had disappeared entirely after the removal of a very rough tooth that continually irritated it. Of the osteoporosis induced by neoplastic growth, Dr. Freeman said that union took place much more frequently than was generally supposed. He showed a striking specimen of this in a firmly united femur, in which union had taken place despite the neoplastic growth. Nor was this union composed of spicules merely, as had been taught.

The remaining papers were read by title, as follows: "Multiple Coccygeal Fibromata," by Dr. H. R. Wharton, of Philadelphia; "The Removal of the Seminal Vesicle," by Dr. N. B. Carson, of St. Louis; "Complete Absence of the Uterus and Vagina, with Creation of New Vagina," by Dr. N. B. Carson, of St. Louis; "A Study of Twenty-Four Cases of Laparotomy for Peritoneal Infection in Typhoid Fever," reported by Drs. George B. Shattuck, J. Collins Warren, and Farrer Cobb, committee of the Boston Society for Medical Improvement, presented by Dr. J. Collins Warren.

Officers Elected.—*President*, Dr. Roswell Park, of Buffalo; *First Vice-President*, Dr. John E. Owens, of Chicago; *Second Vice-President*, Dr. Clayton Parkhill, of Denver; *Secretary*, Dr. H. L. Burrill, of Boston; *Recorder*, Dr. De Forrest Willard, of Philadelphia; *Treasurer*, Dr. George R. Fowler.

The next place of meeting will be Baltimore, Md., May 7, 8, and 9, 1901.

THE AMERICAN GYNECOLOGICAL ASSOCIATION.

Twenty-fifth Annual Meeting, Held at Washington, May 1, 2, and 3, 1900.

First Day (continued)—Tuesday, May 1st—Morning Session.

Discussion on Fecal Fistula.—DR. DUDLEY said that in operating for cancer, and in breaking up the adhesions, he had broken the small intestine in two. He had put in a Murphy button. He could not remove the uterus, even the rectum being involved, so he looked upon the case as helpless. The Murphy button was recovered, having worked down to the rectum and out through the fistula behind the uterus. The fistula healed, and the woman recovered.

DR. MUNDÉ said he had understood his friend, Dr. Noble, to say that fistula was always the result of unclean surgery, and while this was generally true, still sometimes fecal fistulæ did occur when the surgery had been perfectly clean. He had had within a year three cases of fistula resulting from intentional opening of the intestines to relieve obstruction to the bowels tending to general peritonitis following some abdominal operation. In the first case a Murphy-button operation was performed, as the fistula refused to close spontaneously. The patient did not survive the second operation. In the second case the patient recovered. The woman had fecal fistula through the vagina following hysterectomy for double intraligamentous abscesses. This fecal fistula in the vagina closed spontaneously, but the abdominal fistula was so large that after two attempts to close by freshening the intestinal suture through the wound it was resected and the Murphy button applied. In one case of fistula above the sigmoid in which the gut was adherent the layer operation gave a cure. In another Szymanowski's operation was performed, which consisted in paring the one side of the skin and sliding it under the other lifted-up side. This gave complete closure of the open gut. He agreed with Dr. Currier that it was well to wait in fistula of the small intestine; but with fistula of the large bowel the abdomen should be opened.

DR. MANN was disposed to be very conservative in his management, giving the fistula a long time to heal. With the small intestine the condition was somewhat different; the opening would not heal as well as one of the large. The farther up the lesion in the small intestine the less likelihood was there of healing. The nearer to the stomach the harder was it for healing to occur; the gastric juices seemed to interfere with the reparatory process. Therefore it was almost always necessary to open the abdomen in these fistulæ of the small intestine. Further treatment depended upon the size of the opening; if close to the mesentery, it would be dangerous to sew it. If the opening was large, it could not be sewed for fear of stricture. In these cases we were obliged to resect. In one or two cases the result had been satisfactory from a plastic operation on the abdomen without opening the abdomen and cutting down upon the intestines.

DR. PETERSON described a case of fecal fistula which had remained open for a year, at which time he had removed the uterus, hoping to close it from below. This had failed. Under these conditions it seemed to him very dangerous to advise patients to undergo abdominal operations when the fistula was low down.

DR. I. S. STONE said, in closing, that the deeper fistulæ along the sigmoid and the rectum were those which gave the most trouble. In regard to the claim of priority made for Lawson Tait and Greig Smith in the method he had pursued, he replied that he could not see how the method was a typical flange suture. Dr. Mundé's method was applicable in a large number of fistulæ in which the sinus was uncontaminated with fecal matter. In the presence of fecal discharge his own method had the advantage of dividing off the fascia and leaving an opening entirely clean.

The Remote Results of Conservative Operations on the Ovaries and Tubes: An Analysis of Eighty-five Cases.—DR. W. L. BURRAGE read this paper. He said he had performed one hundred and thirty-seven operations on diseased uterine appendages with the object of preserving one ovary or a portion or portions of one or both ovaries with their tubes, or as much of the tubes as was reasonably normal in appearance. In eighty-five of these reliable information as to the present condition could be obtained at least a year after operation, and the results were included in the tables accompanying the paper, the cases being divided into the more severe and the less severe. In comparing the two it was found that gonorrhœa and syphilis were more prevalent, and that the symptoms had resulted more frequently from difficult labors or abortions among the more severe, and that the tubes were closed in a majority of the more severe, whereas they were open in all but one of the less severe. Pregnancy followed operation in four of the more severe and in all of the less severe. In none of the cases in which the closed tubes had been opened and new ostia formed did pregnancy follow operation. In all of the cases of subsequent pregnancy in both classes, except two of the less severe, the patients had had previous pregnancies. Anatomical cure was recorded in thirty-three out of fifty-seven cases which came under observation, and symptomatic cure in sixty out of eighty-five cases. It was advisable to do conservative operations in all cases in which the ovaries and tubes were not hopelessly diseased in all parts of their structure, except on patients who were near the menopause, on patients who had pronounced gonorrhœa of long standing, and on the rare cases of malignant disease. With the present methods of performing resection of the tubes, if both tubes were found closed subsequent pregnancy was not to be expected. In severe grades of inflammation of the appendages irrespective of causation, if the ostium abdominale of one tube was patent the prospect of subsequent pregnancy after the preservation of a portion of the ovary was about one in four and a quarter, or 23.5 per cent. In less severe grades of inflammation under similar conditions of tube and ovary, the prospect of subsequent pregnancy was about one in two and a quarter, or forty-four per cent. In women who had borne children, in both classes, subsequent pregnancy might be expected in thirty-five per cent., whereas in previously sterile women it might be looked for in only five per cent.

DR. EDWARDS said that if one thing was more important, it was the tube rather than the ovary. He would always leave the tube, for nature did a wonderful amount of repairing. He recalled two cases of unmarried women, past the age of thirty years, who married after he had operated, and in both cases the ovary had been buried down below the cul-de-sac. Such women should have the benefit of the operation as much as if they were younger.

DR. DUDLEY said that last year he had reported one hundred and twenty-three cases of such operations and this year one hundred and thirty-eight without death. In a case of double pyosalpinx he had taken the tube off, left the ovary hanging, and brought the uterus up and split the fundus in two. He was absolutely sure that the ovary grafted, and to day the patient was menstruating every twenty-eight days. He had collected five such cases, and in all of them he was sure the ovary had grafted. Two of the women were menstruating; in one only five weeks had elasped. He was of the opinion that the function of menstruation should be conserved, aside from its effects in preventing reflex disturbances.

Dr. Noble asked why Dr. Dudley cut the ovary loose from the natural blood supply if his only object was to retain the influence of the ovary; also if he put it in the uterus to see if pregnancy would result.

Dr. Dudley replied that it was to try the experiment of bringing about pregnancy that he had planted the ovary. The woman upon whom he had done the first operation was pregnant two months afterward.

Dr. Philander A. Harris said he was glad to hear Dr. Burrage speak as he had. In these cases there was often no disease in the ovary itself. Aside from a condition in which there was ovarian abscess, and the follicle had at the time of rupture involved or in any way developed abscess, he did not see why we could judge of a condition which had resulted from inflammation. The Graafian follicles might be mistaken for beginning cystic degeneration. For the past two years he had scarcely removed an ovary, the only cases having been those clearly of ovarian abscess, and he knew that pregnancies had occurred subsequently. The personal inferiority a woman felt when menstruation had ceased was a matter not to be forgotten. It was not the mere matter of having children, but there was a personal element to be considered. He was interested to know how many cases of pregnancy had occurred in women from whom both tubes had been amputated close to the uterus.

Dr. H. N. Vineberg congratulated the writer of the paper on his excellent clinical report. He was pleased to see that he did not claim one hundred per cent. of anatomical cures or one hundred per cent. of clinical cures. Speaking in a general way, the class of cases which in his hands had given the poorest results had been those in which the lesions had not been so very severe.

Dr. Mann said he had done a great many conservative operations. One case in point was that of a woman operated on, from whom one tube and ovary were entirely removed, and the other tube and ovary were in bad condition. The tube was opened, and after breaking up the adhesions the ovary and tube were left. The woman married and had had four children, three girls and one boy, which settled the question of sex in regard to one ovary.

Dr. J. Riddle Goffe said he had done nearly one hundred of these conservative operations. His work had been done very largely through the vaginal incision, as he very much preferred that route of attack. When there were large, bulging ovaries, he used the cautery to resect, and when there was a cystic condition he used the cautery to burn out the cyst.

Dr. Burrage said he had operated twice on cases in which there was no symptomatic and anatomical cure, though there were several other cases in which operation was required. Here the patients would not be operated upon. He had used the cautery on many cystic ovaries after the manner described by Dr. Goffe. He had seen no case of pregnancy follow amputation of both tubes, or when both tubes were closed. He had had pronounced neurasthenics above the age of thirty-five years, and it seemed that complete total removal or no operation was indicated. They did not do well after resections. Careful bacteriological work in this line was needed in order to determine upon which cases to operate from the gross appearance. Few would wish to do an operation when tuberculosis was pronounced.

Internal Secretion of the Ovary.—Dr. A. W. Johnstone, of Cincinnati, read this paper. Retained secretions, he said, were the causes of nearly all nervous conditions. There was no proof that the ovary had any other function than the manufacture of eggs. For fifty years we had known that the ovary was active during intra-uterine life, and that it began to ripen Graafian follicles at the sixth month of gestation; that these ripened rather rapidly until after birth; that during infancy the Graafian follicles still ripened occasionally, but not so rapidly as before birth, and persisted in the same ratio up to puberty. At puberty the follicles ripened more rapidly, but at no time did they amount to as many as the number of menstruations in a year. During and after the menopause the Graafian follicles still continued to ripen. Of all the ovaries that he had removed after the menopause, he had never found one that did not possess a small number of Graafian follicles in an immature state, and he had frequently found those that had recently ruptured. The ovary was in no sense a gland. Its epithelium was arranged for the purpose of being cast out and lost, and it was not so placed that its secretion, if it had any, could be absorbed either by ducts or blood-vessels. The adherents of the internal-secretion theory claimed that it was like the suprarenal, the thymus, or thyroid gland. This he could state positively was not correct. The thymus gland was nothing but a larger lymphatic gland. It did the work of the lymphatic structures during intra-uterine life. Its lymph vessels were just the same as those of the axilla or groin. The thymus gland and suprarenal capsule had no lymphatics that amounted to much, but a very rich supply of blood-vessels; each epithelial cell was closely approximated to a venous radical, thus providing for a rapid absorption of whatever secretion its cells might make. So far as we know, these cells were never entirely removed except by a low form of colloid degeneration, which material was readily absorbed by the blood-vessels close to it. But the ovary was a true duct through which its epithelium when cast out passed off *en masse* to the outer world. If it was a lack of an internal secretion that caused the nervous menstruation disturbances of the menopause, why was it that the little girl did not have them; why was it that delayed menstruation in a child-bearing woman would produce identically the same symptoms as those of the menopause? He would lay it down as a rule, that if a woman's menstruation was delayed for any reason except pregnancy, she was apt to have symptoms closely approximating those of the change of life. Hence he believed that the internal secretion of the ovary was a myth.

Afternoon Session.

The Technique, Indications, and Ultimate Results of Suturing the Round Ligaments to the Vaginal Wall for Retroversions and Flexions of the Uterus.—Dr. Hiram N. Vineberg, of New York, read this paper. He deemed it necessary again to describe the technique in detail, as he had found that the method had not been correctly understood. The patient was prepared as she would be for a vaginal hysterectomy. He then described the several steps of the operation in minute detail. When the uterus was unusually large and heavy, or when the utero-rectal ligaments were put in high tension by anteverting the uterus, it was wise, according to his experience, to employ a single uterine fixation suture in addition to the round-ligament sutures. This suture should not be placed too high upon the uterine wall, in order to avoid the possibility of dystocia in the event of pregnancy. Any operation on the cervix that might be called for was now done, and the posterior vaginal wall or perineum subjected to any plastic operation that might be deemed necessary. The patient was kept in bed for twelve days, when the round-ligament sutures could be removed, with the uterine suture if present. With very few exceptions a curettage preceded the operation. He had performed anterior and posterior colporrhaphy in fourteen cases, and amputation of the cervix in seventeen cases; trachelorrhaphy in six cases; Tait's operation for complete laceration of the perineum in two cases; excision of a vaginal cyst in two cases; salpingo-oöphorectomy in five cases; ovariotomy in two cases; conservative surgery upon the tubes and ovaries in twenty-five. Thus, in sixty-four per cent. some surgical work upon the adnexa was found necessary. The results showed no mortality in the fifty-three consecutive cases. He drew attention to the fact that in every instance the peritoneum was opened and the adnexa were visually inspected. Convalescence was uneventful in forty-eight cases. In five cases there were some complications. In only one case was there an absolute failure, the uterus being found in retroversion six weeks after the operation. The indications and contraindications for the operation were given in detail.

Dr. Currier thought that fixation of the uterus in this way merely by suturing the round ligament did not give much to hold it forward, and thought it could be done better through the abdomen. His own idea was to limit this operation to those cases in which another operation was necessary. As an operation of election when no other operation was required on the uterus or perineum, he preferred very much opening the abdomen, rectifying any difficulty, and then, if desired, confining the operation to the round ligaments, which could be doubled on themselves and turned two or three different ways.

Dr. Sutton spoke of having seen Dr. Vineberg carry out the procedure described, and had since repeated it with uniformly good results. He expressed the hope that soon the abdomen would not be opened so often as now, since these conditions could be attacked through the vagina, and the uterus turned out and myomectomy or supravaginal hysterectomy done; and that the various diseases of the ovaries would be attacked almost exclusively by the vaginal route. He was the more persuaded that this time would come since the French and American operators were removing large fibroids by the vagina after reduction by morcellement.

Dr. J. W. Bovée stated that as a matter of principle he had little use for the shortening of the round ligaments, stating that in his opinion the Alexander operation possessed an advantage over the shortening, inasmuch as it did not require the opening of the peritoneal cavity. He thought there was danger in following these operations of losing track of the fact that most of the cases of dislocation of the uterus were due either to injuries to pelvic fascia, or in the nullipara to abnormal attachment of the ligaments to the uterus. He thought the point of necessity was to adjust the ligaments. Constipation and over-distention of the bladder lessened the efficacy of the shortening of the round ligaments.

Second Day—Wednesday, May 2d—Morning Session.

The meeting was called to order at nine o'clock.

The discussion of Dr. Vineberg's paper was continued.

Dr. J. Riddle Goffe, in answer to Dr. Sutton's hope that all pelvic work would be done through the vagina, expressed the belief that he would not have to wait very long. He had been doing the work for the last three years, and had taken the position that no man was justified in doing laparotomy until he had endeavored to relieve the patient by a vaginal incision. He had found that disease confined within the pelvis could be reached just as effectually through the vagina as through the abdominal incision, and stated that he had covered through the vagina almost every condition that existed in the pathological pelvis. In only one case within the last few years had he been compelled to resort to laparotomy to complete the work. He had removed seven fibroid tumors by myomectomy through the vagina. In these cases there had been retroversion at the same time, which was relieved by shortening the round ligaments after doing myomectomy.

Dr. Vineberg, in closing the discussion, said that he had tried to limit the operation to certain cases and still thought that the cases might require to be selected for the vaginal route; that some cases were best approached from the abdomen. He had frequently removed small fibroids through the vaginal incision.

A paper entitled "A Comparison of Vaginal and Abdominal Operations," by Dr. G. Richelot, of Paris, was read by title.

Demonstrations of Casts Illustrating the Anatomy of Pregnancy and Labor, also Models Used in Gynæcological Teaching.—Dr. J. Clarence Webster, of Chicago, gave this demonstration. He offered for inspection these casts, which had much value in teaching. No work of this kind had been done in America except that done by Dr. William Lusk in New York two years ago. Many clinical observations made by Dr. Webster in regard to the topography of pregnancy had been reproduced in frozen sections. The series included casts illustrating a vertical mesial section of the pelvis, in a woman who died of pernicious vomiting; another showing the beginning of the fifth month of pregnancy; another showing the beginning of the eighth month of pregnancy; a cast of the amniotic cavity at the beginning of the eighth month of pregnancy; a cast showing labor in the advanced second stage; also one with the fœtus *in situ*.

Dr. Mann desired to know whether these models had been put upon the market, and whether it would be possible for teachers of gynæcology to procure them.

Dr. Webster replied that he was under the impression that the Italian moulds had been kept by the makers, and that he had not had sufficient time to see whether they could be reproduced.

Dr. Mann suggested that some arrangement be made by which reproductions could be obtained.

Dr. Buckmaster spoke of a way of reproducing the method of an operation by paraffin. The cervix and pelvic floor, or whatever part desired, was covered with the paraffin, and by placing plaster over this a perfect cast could be obtained without discomfort to the patient.

A paper by Dr. E. E. Montgomery, of Philadelphia, on "Combined Nephrectomy and Ureterectomy" was read by title.

The Anastomosis of the Ureters with the Intestines: An Historical and Experimental Research.—Dr. Reuben Peterson, of Chicago, read this paper. He stated that anastomosis of the ureters with the experimental work forming the basis of this article was undertaken with the view of studying the changes resulting from anastomosing the ureter with the intestinal tract, and of determining whether the procedure could with safety be employed in human beings. The first part of the article was devoted to an exhaustive review of the literature; the second part was given to the description of the author's own experiments, from which, together with the work of others, general conclusions had been drawn. The most striking fact, in the writer's opinion, yielded by a study of the experimental work was the exceptionally high mortality attending the operation, whether one or both ureters were implanted in the bowel. Out of sixty dogs operated on by the various experimenters, when one ureter was implanted in the intestine thirty-five recovered, a mortality of sixty-one per cent. Out of sixty-five dogs undergoing bilateral ureteral anastomosis only eight survived, a mortality of eighty-seven per cent. The majority of deaths resulted from peritonitis through a giving-way of the uretero-rectal stitches and the subsequent escape of the urine into the peritoneal cavity; or an overwhelming infection of the kidney ascribed to nephritis or uræmia. The method which called for the least amount of suturing of the ureter itself would be found to give the best results. In none of the cases operated upon was it demonstrated that the kidney was normal after the corresponding ureter had been implanted in the rectum. The speaker then gave a short abstract of the twenty-eight uretero-intestinal anastomoses in man, showing the primary mortality of thirty-two per cent. to be high. The subsequent history of the successful cases placed the operation in a still more unfavorable light. His experimental work, covering a period of eighteen months, was given in detail. Three series of experiments were conducted: (1) Bilateral uretero-intestinal anastomosis; (2) lateral uretero-intestinal anastomosis; (3) uretero-trigono-intestinal anastomosis. The general conclusions were that the primary mortality of the uretero-intestinal anastomosis both in experimental work on animals and in man was exceedingly high; that all efforts to prevent ascending renal infection in animals or in man had proved futile; that it was impossible to determine the extent of the infection, and that the operation was unjustifiable either for the purpose of making the patient more comfortable or for malignant disease of the bladder.

Dr. Ford, of Utica, referred, in the discussion following, to a case illustrating the toleration of the bowel for continuous service as a bladder. The case was that of a young girl with total suppression of urine lasting over a week. There was no history of stone, and after six weeks she recovered without nephritis. She passed all the urine through the bowel, and was in comparatively good health.

A paper by Dr. George M. Edebohls, of New York, on "Migrated Ovarian Tumors," was read by title, as was also a paper by Dr. J. W. Bovée, of Washington, D. C., entitled "A Critical Survey of Ureteral Implantation."

The Evolution of My Technique in the Treatment of Fibroid Uterine Tumors.—Dr. Howard A. Kelly was the author of this paper. He referred to the fact that it was three years since their fellow-member, Dr. Charles P. Noble, had given an admirable historical résumé of the evolution of the various methods of treating the fibroid uterine tumors, from the earliest efforts in the fifties down to the perfected technique of his own work in the Kensington Hospital for Women. Inasmuch as Dr. Kelly had been closely connected with the development of this subject since his first publication in *The American Journal of Obstetrics*, January, 1886, he thought it might be of more than personal interest to trace his work in the successive advances up to his present, as he believed, perfected technique, and he expressed the belief that if each member would do the same much valuable and interesting information would be available. One of his first operations was an atypical one, performed September 6, 1884, on a patient who had suffered from severe bleeding from several sessile fibroid tumors occupying the lower segment of the uterus. The wound was closed with a glass drainage tube, through which the pelvis was repeatedly washed out with weak carbolized water for ten days, when it was removed. The patient recovered with a large ventral hernia, which she still had ten years later. The next operation was more radical. In this he adopted in several instances the treatment advocated by Hegar, consisting in the control of the vascular supply of the stump by means of a rubber mass ligature. This plan involved far less risk to life than the more ideal method of Schröder. The author's next advance was described in a paper entitled "A New Method of Performing Hystero-Myomectomy," being an address delivered before the College of Physicians of Philadelphia, January 2, 1889. He there advocated the plan successfully carried out October 10, 1888, of tying off the broad ligament, controlling the circulation from the uterine vessels by means of a temporary rubber ligature; cupping out the stump; turning out the cervical mucosa, and obliterating the raw cupped surface of the cervical stump by means of several rows of buried continuous catgut sutures. Most important of all Dr. Kelly considered the description of the method of controlling the uterine vessels, which was detailed. and which was considered a remarkable advance upon anything which had preceded. This met the objection to the Hegar operation by doing away with the rubber ligature, and was the method practised by the writer since that date. Dr. Kelly detailed his method briefly in dealing with very difficult cases, such as large adherent tumors. There were three ways of dealing with these tumors and meeting the complications: (1) By median sagittal bisection of the uterus with the tumor; (2) by a coronal bisection of the uterus in its cervical portion; (3) by a bisection of the tumor alone. He then stated that the situation and the relations of the tumor should be thoroughly studied after the abdomen was opened before attempting its removal. The principle of the operation was the same in all cases. The method of enucleation was to seek first to isolate and ligate the ovarian vessels of one side; then to expose the uterine vessels of the same side; then to cut across the cervix, clamping the opposite uterine artery, the round ligament, and lastly the ovarian vessels.

The President's Address.—The president, Dr. George J. Engelmann, of Boston, in his address gave an historical review of the various periods in gynæcological progress through which we have passed in the last twenty-five years. He believed that Robert Battey, by teaching that the comparatively normal organs could be removed with impunity, opened the way for the successful surgical procedures of to-day. Our methods now should be to reduce the morbidity as we had reduced the mortality. He referred to the work which the society had done in inquiry, investigation, and observation, and thought the Transactions might fairly represent the national contributions to gynæcology. The trend of modern medicine was toward research for cause and prevention. The first step in prevention was the study of condition and cause. The main cause of suffering would be found upon the great waves of a woman's life—puberty, menstruation, labor, and the menopause. Statistics were given to show the tremendous susceptibility and almost feverish activity of the system in the prepubertal period. Statistical tables with diagrams were used to illustrate the increased blood tension, temperature, nerve excitability, and muscular power before, during, and after the menopause.

An Appreciation of Kelly's Method of Removing the Fibroid Uterus by the Abdomen.—Dr. A. Lapthorn Smith, of Montreal, presented this paper. Twenty years ago the writer was strongly opposed to operative treatment of fibroids on account of the high mortality then prevailing among the best operators. Ten years ago he became a strong advocate of Apostoli's method of electrical treatment, by which he had cured the hemorrhage permanently in sixty-three out of a hundred and two cases in ten years. Eight years ago Price lowered the mortality enough to induce him to operate in certain cases with the serre-nœud. Baer further reduced the mortality, and he adopted his method and operated oftener. Three years ago Kelly perfected an ideal method which had almost no mortality, and which the author had adopted, and to which he gave the preference over all other treatment in every patient with fibroid who suffered enough to consult him. He claimed that he had acted consistently throughout, being guided by the one test question, "What was the mortality?" In his last ten successive cases, seven last year and three this year, all the patients had recovered. Therefore the operation was now almost devoid of danger, while it was absolutely effective. Kelly's method was by far the best, and to it was due, he believed, his absence of mortality in these ten cases. The great advantage of Kelly's method was that we began on the easy side, and after securely tying the ovarian, round ligament, and uterine arteries, and separating the bladder, we cut across the cervix and rolled the tumor out, thus obtaining plenty of room to tie the arteries from below upward. Another great advantage of this method was that there was much less danger of injuring the ureters. This accident was most likely to happen on the most difficult side; that is, the side where the tumor filled all the space between the uterus and the wall of the pelvis. But it was precisely on this side that the tumor was dragged away from the ureter while it was being rolled out, and by the time that it became necessary to cut anything on that side the ureter was at least two inches away and quite out of danger. Doyen's method had this advantage on both sides because he pulled the tumor off the bladder and ureters, and from the first cut he was getting farther and farther away from the bladder and ureters. But Doyen's method had the great objection of opening the vagina and thereby increasing the time of anæsthesia, loss of blood, and risk of infection, besides the æsthetic one of shortening the vagina. The author laid even greater stress than Kelly did upon the importance of feeling for each individual artery and tying it before cutting it, and then putting a second ligature on it, as the first one might loosen after the tension of the tumor had been removed. He also strongly advised chromicized catgut prepared by each operator himself, or else Red Cross cumol catgut prepared by Johnson, of New Brunswick, N. J., which he had found reliable. Besides the six primal arteries there were two small arteries which required tying on each side of the cervix. There was no need of disinfecting the stump beyond wiping away the little plug of mucus; but the cervix should be hollowed out so as to make anterior and posterior flaps, which were securely brought together before the peritoneum was sewed up. The omentum, if long enough, should be brought down to meet this line of suture, thereby preventing the intestine from sticking to it or to the abdominal incision. The speaker was opposed to leaving the ovaries and tubes, although he admitted that in young women so doing diminished the discomforts of the premature menopause. But in the majority of cases the appendages were diseased, and we ran the risk of the whole success of the operation being marred by leaving in organs which would sooner or later cause more symptoms than did the fibroid itself. His experience of leaving in ovaries or portions of ovaries had been most unfortunate, having received no thanks for his conscientious endeavors but a great deal of blame for having failed to cure the pain, which in the patient's estimation was much more important than the tumor. He was also much opposed to myomectomy; the operation was quite as dangerous as hysterectomy; there was very seldom any reason for it, as most of the women who had fibroids were at too advanced an age to raise children to advantage, or had passed the child-bearing age altogether. After submitting to such a serious operation the patient had a right to be guaranteed against a second or third one for the same disease. So many women had been disappointed by these incomplete or so-called conservative operations that their friends who really could be cured by an operation hesitated to undergo it. He would make an exception, of course, in case there was apparently only a single polypus no matter how large, or a single pediculated subperitoneal tumor. He held the opinion that all fibroid uteri should be removed as soon as discovered, because the woman with a fibroid was liable not only to the hemorrhage, which might not be great, but to reflex disturbances of digestion and circulation. Besides, every day it grew its removal became more dangerous, and the chances of its becoming malignant were greater. He was opposed to a preliminary curetting because it was unnecessary, and second, because when done it was seldom done effectually; having examined immediately after removal a fibroid uterus which had been curetted just before, he had found only about a twentieth part of the uterine mucosa removed. He was strongly opposed to vaginal morcellement, which was not to be compared with Kelly's method. It was much more dangerous, much more difficult, and kept the patient a much longer time under the anæsthetic. The operation was carried on in the dark, and the ureters were frequently wounded, while complications such as adhesions of the vermiform appendix and tears of the intestines, which were easily dealt with by the abdomen, with the patient in the Trendelenburg posture, were almost impossible to manage when working from the vagina. Moreover, nearly all women with fibroids were nulliparous, and the vagina was consequently narrow; they were nearly all elderly, and the passage was consequently inextensible. No more unsuitable class of patients could therefore be chosen for this difficult vaginal work. Besides, in morcellement clamps were used, and these compressed the nerves in the broad ligament, and a woman who had been operated upon with clamps took much longer time to recover than one who had only the arteries tied. Also, with clamps the peritoneum was left open, and, worst of all, the air of the hospital was contaminated with the sloughing tissue in the vagina. The author strongly advised the closure of the abdomen with through-and-through silkworm-gut sutures left in for three or, better still, four weeks. If they were not tied too tightly, and the wound was dressed with boracic acid in abundance, the one dressing or at most two dressings would suffice from the beginning to the end of the case. Besides, these sutures could be passed very quickly, thus saving ten minutes in the duration of the anæsthesia.

Intra-Abdominal Amputation of the Uterus; a Modification of Hysterectomy.—Dr. F. H. Davenport, of Boston, read this paper. He stated that the indications for hysterectomy were pretty well established, and that interest was now centred upon the technique. He called attention to a modification of so-called abdominal hysterectomy which he had practised for about two years. When it was possible in a young married woman to leave the cervix, he preferred to do so; hence for suitable cases he chose the abdominal route. He operated by the vagina for cancer of either the cervix or body. If a patient who was single or near or past the menopause, with a small or medium-sized fibroid which was non-adherent, objected to the scar of the abdominal operation, he operated by the vagina. On the other hand, in a young married woman he chose the abdominal route; it was of a good deal of importance that the vagina be preserved. When the uterus was to be removed for chronic inflammation or its results there was usually concomitant disease of the appendages, and the abdominal route gave full opportunity for seeing the exact condition of all the pelvic organs. The essential feature in which his method differed from that usually employed was that the uterine arteries were not ligated. He then described his method in detail. His results had been satisfactory.

The papers of Drs. Kelly, Smith, and Davenport were discussed jointly.

Dr. W. R. Pryor stated that the essence of the operation was the reduction of the mass by morcellement to produce a symmetrical tumor. The ovarian arteries being tied, the anterior wall of the uterus was split through; traction forceps were applied, and the intra-ligamentary nodule was seized and taken out of its bed. The moment the nodule was taken out the side from which it was taken became symmetrical. If the nodule was in front it could best be approached by tilting the tumor forward.

Dr. Gordon said that the continuous suture of which Dr. Davenport spoke was the one he had followed since he had been doing hysterectomy. He objected to the use of chromicized gut as used by Dr. Smith, for the reason that its absorption required a long time and sometimes never occurred. He further objected to Dr. Davenport's continuous suture with silk. He had used nothing but catgut since 1884, except in the through-and-through suture of silkworm gut in abdominal section.

Dr. Mann felt that the trend of sentiment seemed so decidedly in favor of the method pursued by Dr. Pryor and Dr. Kelly that he hesitated to mention a different method which made the operation easier. In a case in which the tumor was held down in the pelvis by the broad ligaments he thought that if the upper part of the broad ligaments was cut first and then the tissues cut across, the tumor would come up out of the pelvis and would be more easily gotten out.

Dr. J. M. Baldy referred to a case he had had within the past week, of a fibroid tumor in which the nodule extended down over the vagina. He was forced to approach it posteriorly instead of anteriorly as Dr. Kelly had done. Enucleation was performed similarly to the method claimed by Doyen. As to cutting down one side, amputating, and coming up on the other side, he had done the operation shortly after Dr. Pryor, and considered it exceedingly dangerous and one to be used only by the most expert.

Dr. Reynolds considered the principal point in the method of Dr. Davenport to be that of tying the uterine artery. The operation was thus made much simpler.

Dr. Johnstone thought that most of Dr. Kelly's troubles were of his own making; that when the uterus was wedged down in the pelvis, and there was danger of hemorrhage, the arteries should first be tied, thereby cutting off the blood supply as effectually as a plumber turned water off from the yard.

Dr. Kelly, in closing, called attention to the fact that the bisection method was applicable to all inflammatory cases. There was no risk to the ureters on the side if the bladder and the tissues were pushed down. He considered it safe to cut the uterine arteries and clamp afterward.

Third Day—Thursday, May 3d—Morning Session.

The discussion of the papers of Drs. F. H. Davenport, Howard A. Kelly, and A. Lapthorn Smith was resumed.

Dr. Smith emphasized the great advantage he had found in the operation by going down on one side, the easy side, and coming up on the other. He considered it important to leave the cervix. He believed that Doyen's reputed high mortality was due to the fact that he took out the cervix. He thought the risk of infection from hemorrhage and the length of operation were thereby increased. He had reported ten cases of large fibroids removed in this way, all of which resulted in recovery. He used chromicized catgut which had been in potassium solution for one hour. In the cervix this lasted but ten days. He would never leave any kind of silk in the abdomen. He agreed with Dr. Gordon that there was nothing like silkworm gut for closing the abdomen, and with it he had not had a hernia for four years. He did not concur in Dr. Baldy's opinion that this operation was made for only the most expert operators.

Bronchial Disease Not Invariably a Contraindication for Ether Anæsthesia in Abdominal Surgery.—In this paper Dr. T. A. Reamy, of Cincinnati, stated that his personal experience with surgical anæsthesia covered eight thousand cases; his obstetrical work, three thousand deliveries. Two thousand of these were under chloroform anæsthesia. For surgical work he considered ether in every way preferable as an anæsthetic. He had, however, never lost a patient under either ether or chloroform. He considered the prejudice against the use of ether in the presence of acute, subacute, or even chronic bronchitis largely unfounded, provided proper conditions were observed in its administration. He insisted that the inhaler must be so constructed as to permit reinhalation of the vapor, which was therefore mixed, from the beginning to the end of the operation, with carbon dioxide. He objected to most of the inhalers in use, and presented a simple one of special form constructed by his nurses, and which answered the purpose perfectly. It was likewise cheap and clean. The ether was poured on absorbent cotton in the bottom of the inhaler. No additional ether was used unless the operation lasted more than forty minutes. He began the administration of the anæsthetic himself. He regarded the assuring words of the surgeon to the patient, as the inhalation commenced, as very important. He insisted upon great care in the protection of the patient on removal from the operating-room to her own room, the temperature of which must be for several hours not below 80° F. He had witnessed but one case in which pneumonia was probably produced by ether inhalation. He had seen bronchitis, both acute and chronic, at once cured as a result of ether anæsthesia. In some instances he did not hesitate to administer it to patients suffering with severe bronchorrhœa. He would not use ether in the presence of emphysema. He would not, of course, employ it when the patient was suffering from Bright's disease, but he had rarely seen damage to the kidney follow its administration in properly selected subjects.

Dr. Malcolm McLean, in discussing this paper, pointed out that the elevation of the temperature of the room deserved a great deal of consideration. This he thought was very much overlooked, and he said that trouble following anæsthesia was often attributable to the low temperature of the room. The operator felt comfortable in a temperature of 72° F., but the patient under anæsthesia was not in a safe condition. He also referred to the unnecessary confusion in the etherizing-room, the result being that the patient required much more ether. He considered that with the patient in a secluded place, and without unnecessary intrusion, one-third of the amount of ether generally used would place her under full anæsthesia. This had been his experience for over twenty years. His rule had been never to let a person speak to the patient after the anæsthesia had commenced.

Dr. Philander A. Harris stated that he had had ether administered to himself quite a number of times, and so could corroborate the wisdom of remembering that reference to anything, except just the business of the ether, should be entirely dispensed with. He considered this important not only for the patient's feelings, but in consideration of the ease and advantage with which one could anæsthetize without these disturbing elements.

Dr. Reamy, in closing the discussion, said that conversation in the room was one of the most damaging things that could occur. As a rule his patients did not have the reflex cough, for they were put under the anæsthetic within four to six minutes, in almost every case. The room must be hot, and the ether must be given in the operating-room, that the temperature might be even from beginning to end. The inhaler was not removed unless the patient developed cyanosis.

A paper entitled "The Treatment of Full-Term Ectopic Gestation: Should not the Child Receive More Consideration?" by Dr. Edwin B. Cragin, of New York, was read by title.

The Relationship between Dysmenorrhœa and Appendicitis.—Dr. Archibald McLaren, of St. Paul, read this paper. He considered the influence of pelvic and inflammatory conditions on menstruation. In cases of cystic ovaritis and ovarian abscess he had seen some particularly satisfactory results follow the removal of overlooked appendages. In two hundred laparotomies he had had one hundred and fifty-eight cases in which inflammatory appendages had to be removed, and the appendix showed indications for removal in forty per cent. The conclusion drawn from the histories was that the trouble had originated in the appendix and spread to the ovary and tube. During the same time he had operated on seventeen cases of appendicitis in which there was no evidence of extension of the inflammation. He did not advocate the removal of the appendix in every case. The speaker gave the technique of his earlier operations, and stated that later he had adopted the method of Kelly.

Dr. A. J. C. Skene stated that the relation of appendicitis to dysmenorrhœa was a new idea to him, and he consequently accepted what had been said by the author of the paper as being perfectly reliable science. The paper explained to him certain observations which he had been unable to account for, *i.e.*, ovarian pain undoubtedly caused by appendicitis, the pain in the ovaries being always aggravated at the menstrual period, giving rise to the condition known as dysménorrhœa ovarienne. In those cases the ovarian pain had disappeared when the appendix had been removed. He considered that the extirpation of the appendix was better and more quickly accomplished by the use of the hæmostatic forceps, which had the advantage over other forceps in absolutely and permanently closing the canal of the appendix and the opening into the intestine. By this means there was no ligature to be disposed of, and reopening and establishment of fecal fistulæ were avoided.

Dr. A. Lapthorn Smith's experience coincided with that of Dr. McLaren; in nine or ten cases operated upon for tubal pregnancy or pus tubes he had found the appendix firmly embedded in the tumor. In one case of tubal pregnancy the specimen could be held up by the appendix. The salpingitis communicated from the appendicitis was probably the cause of the tubal pregnancy. In another case the appendix could be followed by a probe about an inch deep in a mass of exudation. He believed that if the plan of tying the ligature around the appendix and cutting off was abandoned there would be no fecal fistula. Treatment as in a bullet-wound would be the simplest procedure. He regarded constipation a strong factor in the production of infection, bacilli being increased in number in proportion to the number of days the bowels were unmoved. The presence of pus tubes in young women was satisfactorily explained by the appendicitis.

Dr. McLaren, in closing the discussion, considered the point mentioned by Dr. Smith, of young women having pus tubes, very important. He had seen several young women whose reputation had been smirched by the very fact that they had pus tubes, when operation showed appendicitis to be the cause of the suppuration. Such cases were usually confined to the right side. Out of fifty-nine cases he had removed the appendix twenty times. Operation did not affect the mortality. He thought the bullet-wound treatment safer and more surgical than the removal with the cautery.

A paper by Dr. Egbert H. Grandin on "Clinical Data Relating to (*a*) Urinary Toxæmia; (*b*) the Operative Treatment of Uterine Displacements; (*c*) Ectopic Gestation; (*d*) Certain Complications of Uterine Fibroid," was read by title.

A Certain Chart for the Demonstration of Pelvic Asymmetry from a Very Simple Method of External Pelvimetry.—Dr. Philander A. Harris, of Paterson, N. J., demonstrated the use of this chart. He believed that the best interest of the patient and physician demanded the study of pelvic measurements. The instrument employed was exhibited. Dr. Harris also showed photographs exhibiting the advantages of employing certain backgrounds in the photography of pathological specimens.

Dr. E. Van DeWarker said that the shadows which were troublesome in photography were gotten rid of by suspending the specimen in water in the glass tray with the illuminator under it. The effects secured by this arrangement were exceedingly satisfactory.

A Contribution to the Management of Face Presentations, with Report of Two Cases.—Dr. Malcolm McLean, of New York, read this paper. He gave in detail a description of his method of dealing with these faulty presentations. The patient being under full chloroform anæsthesia, the hand was passed carefully within the vulva, with the outside hand seizing the body of the child. In the entire absence of uterine contraction the chin was pushed away from the pelvic brim as much as possible, from the point toward which the chin was pointing in the direction of the occiput, *i.e.*, pushed obliquely from behind forward. At the same time the fingers of the vaginal hand were pushed up alongside of the head in one or other of the oblique diameters of the pelvis, so that they could reach the sub-occipital portion of the head. The thumb at the moment steadied the brow, and with a slight elevated motion imparted to the whole head it was caused to rotate on its axis as described—the chin passing upward above the ischiatic notch as the occiput was drawn down below the pubis. Flexion could be considerably hastened by pressing down the occiput by the outside hand as soon as the face was dislodged from its wrong position. The author detailed cases illustrating the usefulness of the method.

Dr. C. M. Green had always believed it was hardly possible to flex fully the extended head in the pelvis in the way described. He had never seen a face presentation with the chin posterior, with the head within the pelvis, in which he had not succeeded in delivering with forceps, or in allowing the mother to deliver. He had often been asked by students whether in these posterior presentations flexion by the head was not possible, but had always been obliged to say he had never tried it because he had succeeded in rotation of the chin forward by the hand. Everything depended on the relations between the head and the pelvis; if the pelvis was sufficiently large, or the disproportion was not extreme, and the operator was fortunate in having a small hand, he might accomplish it. He thought that much more could be accomplished than was supposed by the use of the hand in the pelvis. He believed the body should be turned at the same time to secure success. He thought that many of these face presentations were due to slight antero-posterior contractions at the brim, and it was a question, unless the child seemed very large, whether it was not wise to let it enter the pelvis.

Dr. R. A. Murray referred to the dictum that when there was irregular presentation of the child there was something faulty in the pelvis, and that the child should always be kept in mind. Examination should be thorough before remedial operation was undertaken. The mere introduction of the hand to determine the cause gave means to determine the size of the pelvis and relative size of the head to the pelvis, and so would be a guide to remedying these faulty presentations. To wait for the effective application of the forceps exhausted the patient, and the child was almost invariably lost unless it was very small. Schatz's method would be very good, but for the fact that it had to be applied at the superior strait. He called attention to the fact that when the operation was difficult on account of the head being wedged, and when there was difficulty in getting the patient under anæsthesia, very great aid could be obtained by putting her either in the knee-chest position or in Sims' position, in order to take away the head from the superior strait.

Dr. Edward Reynolds said that in the treatment of the presentation of the face posteriorly in the pelvis the suggestion which he had borne in mind for some years was that if the ordinary manipulative corrections of the presentation failed he should expect to render them easy by symphyseotomy.

Dr. McLean, in closing, emphasized the point that in these cases the head had the ordinary relation to the size of the pelvis. This was mentioned because since the author's first report it had been asserted by two or three prominent teachers that there must have been great disproportion between the size of the head and the size of the pelvis. The proportions were normal or below the normal relations as regards the width of the conjugate in the mother. In other words, the conditions were those of the average; he simply took advantage of the flexible portions of the pelvic passage.

A paper by Dr. E. P. Davis, of Philadelphia, on "The Pernicious Nausea of Pregnancy, with a Report of Cases and Autopsy," was read by title.

At the close of the scientific business of the society the retiring president, Dr. George J. Engelmann, thanked the members for courteous helpfulness which had made the duties of the president pleasant and easy.

The newly elected president, Dr. E. Van DeWarker, of Syracuse, was then introduced.

Other officers elected were: *Vice-Presidents*, Drs. Charles Jewett and R. B. Maury; *Secretary*, Dr. J. Riddle Goffe (re-elected); *Treasurer*, Dr. J. Montgomery Baldy. The other members of the council were Drs. M. D. Mann, W. R. Pryor, S. C. Gordon, and J. T. Johnson.

The place selected for the meeting in 1901 was Chicago.

Afternoon Session.

The afternoon of the closing day of the meeting was devoted to anniversary exercises at Marshall Hall, on the Potomac.

Dr. T. Addis Emmet, of New York, read a paper entitled "Personal Reminiscences Associated with the Progress of Gynæcology."

"The Status of Gynæcology in 1876 and in 1900" was the subject of a paper by Dr. Alexander J. C. Skene, of Brooklyn, N. Y.

Dr. James R. Chadwick gave some "Reminiscences of the Foundation and Early Years of the Society."

The programme was completed on the boat on the return to Washington, by a paper by Dr. E. Van De Warker, of Syracuse, N. Y., on "The Personal Factor in the Work of the American Gynecological Society," and a poem entitled "Some Kaleidoscope Pictures in Rhyme," by Dr. Thaddeus A. Reamy, of Cincinnati.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2d.

Adiposis Dolorosa.—Dr. F. X. Dercum, of Philadelphia, read the report of a case of adiposis dolorosa, with autopsy. The patient died from fatty degeneration of the heart. There was fatty infiltration of all of the internal organs and the muscular system. Microscopical examination revealed interstitial neuritis of the peripheral nerves, degeneration of the columns of Goll in the cervico-dorsal region, and unusual pigmentation of the cortical cells in the cerebrum. The pituitary gland was normal. The thyroid structure was hypertrophied.

Dr. Charles W. Burr, of Philadelphia, had made an autopsy in a similar case with practically the same findings. There was also a new growth affecting the pituitary body, which was probably the cause of the hydromyelia.

Dr. Dercum mentioned that marked improvement resulted from the administration of thyroid extract.

A discussion of the neuron doctrine in its relationship to diseases of the nervous system followed.

The Anatomico-Cytological Relationship of the Neuron to Disease of the Nervous System.—This was the title of a paper by Dr. L. F. Barker, of Baltimore. The paper dealt with the present status of knowledge of the units in the nervous system. The history of the neuron doctrine was traced. The conception originated with the pathologists (Ford), was supported by the embryological work of His, and by histological studies made by Golgi's method. Waldeyer, in 1891, collected the evidence in favor of the view, and gave to the nerve units the name "neurons." The speaker saw in the neuron doctrine nothing more than the application of the cell doctrine to the nervous system. Until it was shown that the axis cylinder of a nerve fibre and its end-ramifications were integral parts of a single cell, it was impossible to apply the cell doctrine intelligently to the nervous system. The "nerve cell" of the books was only a part of the real nerve cell. The contact theory was regarded as refuted; it was not an integral part of the doctrine of the nerve units or neurons. The retraction theory had never had any adequate basis. The studies of Apàthy and Bethe were regarded as extremely important as bearing upon the intimate relations which existed between the nerve units; they did not interfere in any way with the retention of the idea of the units themselves.

The Pathological Changes in the Neuron in Nervous Disease.—This paper was read by Dr. W. G. Spiller, of Philadelphia. He regarded the limitation of degeneration to certain systems in some nervous diseases as indicative of alteration of distinct groups of neurons, and therefore as evidence that distinct neurons existed. He then discussed the questions: (1) Whether a neuron was affected in its entirety by disease; and (2) whether the disease of one neuron had any influence on another neuron with which it might be functionally related. He attempted to show that when a neuron was injured in any way it suffered alteration in all its parts, although in some cases this alteration might be slight. He took his illustrations chiefly from his own investigations. He referred to complete atrophy of the cells of Clarke's columns from a cervico-thoracic lesion, and spoke of retrograde atrophy, describing a case of chronic neuritis with changes in the cells of origin and one of facial palsy of six months' duration, with changes in the facial nucleus. He described the chromatolysis he had found in the nerve cells of the lower part of the cord after a hip-joint amputation. Cases were reported to show that degeneration of the axon did not occur so promptly as changes in the cell of origin; also two cases of atrophy of the cortical nerve cells from injury of their axons. These and other illustrations were given as evidence that the structure known as a neuron suffered more or less in its entirety when diseased, and that this involvement was indicative of the functional individuality of the structure. Dr. Spiller then discussed the influence of one neuron upon another. He said he had been unable to find atrophy of the cells of the anterior horn of the cord on the side of the degenerated pyramidal tract in hemiplegia either of cerebral or spinal origin; even in the case of compression of the cervico-thoracic cord in early life, in which the cells of Clarke's column had disappeared, the cells of the anterior horns were not distinctly diseased. In a case of complete paralysis from unilateral internal hydrocephalus the cells of the anterior horns were not distinctly affected. In three cats in which the posterior roots had been cut he failed to find alteration of the motor spinal cells. In the case of unilateral syringomyelia of the cervical cord, reported previously by Dr. Dercum and himself, in which the posterior roots of one side were destroyed, the cells of the anterior horns were not seriously affected. Dr. Spiller therefore did not believe that injury of the central motor tracts or of the posterior roots had much influence on the cells of the anterior horns. He referred to cases to show that disease of the peripheral motor neuron did not cause degeneration of the central motor neuron. He said he had never seen involvement of the lemniscus following degeneration of the posterior columns, and cited cases to show that two neurons in connection with one another did not degenerate to the same degree and with the same rapidity from one lesion. He concluded, therefore, that a difference in structure must exist at the point where these two neurons came together, and that the essential elements of one neuron were not the same essential elements of another neuron. A study of pathological changes, he believed, afforded considerable evidence of the existence of neurons, and the results obtained in this way must be harmonized with those derived from anatomical investigations.

How Far does the Neuron Doctrine Affect Our Conception of Nervous Disease ?—This was the title of a paper by Dr. B. Sachs, of New York. He concluded that the nerve force must pass from one unit to the other, and that the health of the cell body depended in a great measure on the health of the distal parts. The cell-body was functionally co-ordinate and dependent upon the entire neuron system. He believed that the neuron doctrine had aided our conception of many forms of nervous disease, such as tabes, amyotrophic lateral sclerosis, multiple neuritis, and progressive muscular atrophy.

The Physiological Significance of the Size and Shape of the Neurons.—Dr. H. H. Donaldson, of Chicago, read a paper with this title.

Dr. J. J. Putnam, of Boston, thought we should abandon the notion of the cell-body as a storage centre for memories, etc., as the mechanism acted as a whole.

Dr. F. W. Langdon, of Cincinnati, said that anatomically the doctrine had helped us to make order out of chaos, and had led to better diagnosis and prognosis and possibly to more intelligent treatment.

Dr. Ira Van Gieson, of New York, expressed the view that the fundamental theory of the neuron could not be doubted, and required no defence at the present day. We must depart from morphology and go to physiology for elucidation. As to the theory of neuron retraction, it must proceed from the deductive method.

Dr. Charles K. Mills said that as to nomenclature it would be better to adhere to the term nerve cell or cell body, instead of using confusing terms. The term neuron had done harm in teaching the new doctrine. The facts that had been established must stand. It seemed to him that the nerve cell was nutritionally and ideo-plastically a unit.

Dr. F. X. Dercum considered theories as good working hypotheses, and spoke in support of the retraction theory.

Dr. Morton Prince, of Boston, thought the difference of opinion as to the doctrine was the difference of concept of the neuron theory. It had changed our views in regard to the interpretation of clinical and physiological facts. The retraction theory was valuable as a working hypothesis.

Dr. Joseph Collins, of New York, opposed the retraction theory. He believed the neuron doctrine had aided in the interpretation of many obscure classes of cases as explained by Dr. Sachs.

Third Day—Thursday, May 3d.

Clinical and Anatomical Analysis of Cases of Diffuse Myelitis.—A paper on this subject was read by Drs. J. J. Putnam and E. W. Taylor, of Boston. They expressed the opinion that diffuse myelitis was a distinct disease with clinical and anatomical characteristics, and reported a case which was associated with pernicious anæmia.

Dr. F. W. Langdon said there were two groups of pernicious anæmia in which spinal degeneration occurred in the posterior and lateral columns. This did not occur, however, in every case of pernicious anæmia. In one of his cases mucous colitis was present in conjunction with the spinal degeneration.

Dr. William G. Spiller asked if it was a systemic degeneration or a degeneration from disseminated foci, or a posterior root degeneration.

Dr. Putnam replied that it would seem to be a systemic degeneration. At the present time it was a matter of uncertainty. The anatomical lesions did not explain the clinical symptoms.

Section of the Posterior Spinal Roots.—Dr. Morton Prince, of Boston, read the report of a case in which section of the posterior spinal roots was performed for the relief of pain caused by neuritis of the brachial plexus. The operation was followed by cessation of pain in the affected region. Subsequently Brown-Séquard paralysis developed, involving the same area, and pain occurred in other areas as a result of laminectomy. He thought that one of the dangers of laminectomy was the possibility of an artificial blood-clot being formed in the cord.

Central Fissures of the Brain.—Dr. Burt G. Wilder, of Ithaca, exhibited the brain and gave a revised interpretation of the central fissures of the educated suicide's brain presented to the association in 1894.

The report was discussed by Drs. Langdon, Donaldson, Spiller, Meyer, and Mills.

Malaria Presenting the Symptoms of Multiple Sclerosis, with Necropsy.—Dr. W. G. Spiller referred briefly to some of the clinical cases of paralysis resulting from malaria, and described the following case with the symptoms of multiple sclerosis: A man of middle age, a sailor, under the care of Dr. Dercum, was in good health until about 1890. He then began to have headache, dizziness, and ringing in the ears. These symptoms lasted until 1895, when they were controlled by medicine, but they soon returned. In 1892 he had a slight transitory hemiplegia of the right side. In 1895 he suddenly lost power in the left half of his body, but the attack of paralysis was not accompanied by any loss of consciousness and was of short duration. When he came under observation in 1896, his sway was decidedly increased when the Romberg test was made. He was extremely ataxic in the left lower limb, but not in the right, and he had a very marked intention tremor on the left side. He presented a very somnolent appearance. Marked vertical nystagmus was easily elicited. The speech was scanning. The knee jerk was exaggerated on the right side, but was normal on the left, and ankle clonus was obtained only on the right side. The man died in 1899 after a severe diarrhœa, probably of malarial origin, lasting one week. Fever had been observed only during the last week of the patient's life. The right crossed pyramidal tract was slightly sclerotic, and the sclerosis was traced as high as the left internal capsule. Every capillary of the central nervous system was filled with the æstivo-autumnal form of the malarial parasite containing pigment, and numerous small hemorrhages were found. The capillaries under low power looked as though they had been injected with black powder. The symptoms were those of multiple sclerosis unilateral in type. This was the only case on record of malaria presenting the symptoms of multiple sclerosis in which a necropsy had been obtained. Some clinical cases had been reported. The slight unilateral sclerosis, in the right crossed pyramidal tract was sufficient to prevent tremor and ataxia such as were observed in the left limbs. The symptoms of multiple sclerosis were due to the thrombosis of the capillaries by the parasites and not to areas of sclerosis. The case showed that the disseminated sclerosis of malarial origin was a pseudo-sclerosis.

Dr. Mills said that while malaria was undoubted in this case, it was questionable whether the ataxia was due to a toxæmia, as there were numerous hemorrhagic lesions of small size. In several cases of uræmic hemiplegia gross lesions have been found. The symptoms were not necessarily attributable to the toxæmia. He had seen cases in which the symptoms of tabes were due to malarial poisoning. He referred to a patient with pseudo-tabes who recovered under anti-malarial treatment.

Dr. Langdon spoke of a patient with profound coma and elevation of temperature. Blood examination showed the presence of malarial organisms, and quinine subcutaneously effected a cure.

Multiple Sclerosis with Autopsy.—A paper on this subject with the report of a case was read by Drs. Charles W. Burr and D. J. McCarthy, of Philadelphia. The patient presented, during the course of seven years, the clinical picture of locomotor ataxia; ataxic paraplegia (combined system disease); and finally spastic paraplegia, without at any time having the typical symptoms, intention tremor, nystagmus, scanning speech, etc. The autopsy revealed extensive degeneration of the cortex with proliferation of the glia; sharply cut areas of sclerosis in the brain substance; extensive involvement of the pons, medulla, and spinal cord. None of these lesions produced secondary degeneration. Microscopically the usual sclerotic areas of multiple sclerosis were seen: retention of the axis cylinder in the sclerotic areas with destruction of the myelin was noted. Around the blood-vessels a reticular network of nucleated cells was present, probably due to low-grade irritation of the blood-vessel walls by the growing glia. The interest in the case lay in the fact that with such extensive involvement of pons and medulla there should be no bulbar symptoms, and with extensive involvement of the optic nerves and commissure there should be so little failure of vision.

Dr. Adolf Meyer, of Worcester, Mass., gave a demonstration of a few reconstructions of parts of the nervous system.

Tumor of the Spinal Cord.—This was the title of a paper by Dr. John Jenks Thomas, of Boston. He reported two cases of tumor affecting the spinal cord. The first case was that of a young woman, twenty-one years of age at the onset of the disease, who during the course of ten months gradually became paraplegic. At the time of admission to the hospital the sensory and motor paralysis and the paralysis of the sphincters was practically complete, and certainly so at a later period, and from that time on the patient seemed to have had no pain. Gradually very marked contraction developed, and the patient remained in much the same condition for a period of thirteen years, except for an outbreak of mental trouble with excitement, from which she made a good recovery. Death took place from exhaustion and diffuse nephritis, and chronic cystitis. At the autopsy there was found a tumor of the dura in the mid-dorsal region, which had completely compressed the cord beneath it. The tumor was an endothelioma. The cord was atrophied and showed the usual ascending and descending degeneration of the various tracts. The second case was one of intramedullary glioma in the cervical region in a boy of six years. The symptoms developed after a slight injury, beginning with weakness of the right hand and arm, the left forearm being congenitally absent, and with pain in the shoulder, and rotation of the head to the left. Later the paralysis of the arm became more marked, and there was diminished electrical irritability of the muscles of the arm, and slight paresis of the right leg with increased tendon reflexes in that extremity. Two weeks later, and seven weeks after the onset of the first symptoms, the patient died suddenly with symptoms of interference with respiration. The autopsy showed a glioma of the whole of the cervical enlargement of the cord, into the upper part of which a large hemorrhage had taken place, and with another hemorrhage in the lower part of the growth and in the central part of the cord, extending well down into the thoracic cord. Sudden death from hemorrhage into the tumor was much rarer in cases of tumors of the cord than in those of the brain where it not infrequently occurred, though small hemorrhages into the cord tumors were frequent. The case was also unusual because of the rapid course from the time of the first development of the symptoms, and because of the youth of the patient.

New Members.—The following-named gentlemen were elected to membership: Dr. S. E. Jelliffe, of New York; Dr. J. W. Courtenay, of Boston; Dr. Llewellys F. Barker, of Baltimore; Dr. Pearce Bailey, of New York; Dr. Henry M. Hurd, of Baltimore; Dr. D. J. McCarthy, of Philadelphia.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. G. L. Walton, of Boston; *Vice-Presidents*, Drs. Charles W. Burr, of Philadelphia, and Henry L. Stedman, of Boston; *Council*, Drs. E. D. Fisher, of New York, and F. W. Langdon, of Cincinnati; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

AMERICAN PEDIATRIC SOCIETY.

Twelfth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2d.

The Treatment of Hydrocephalus by Craniectomy.—This paper was by Dr. Edward P. Davis, of Philadelphia. He related the case of an infant six months old. The mother was previously healthy. Two brothers were not well nourished. The birth was easy and natural, the child weighing five and one-half pounds. When six months old it weighed nine and one-half pounds, and was 54 cm. long; chest circumference, 34 cm.; cranium, 41 cm. There were no teeth. The general appearance was that of a case of intrauterine rachitis. Double inguinal hernia existed. The child was stupid and showed that there was intracranial pressure. The child was trephined without trouble, and a sterile silver cannula introduced to draw off the clear serum. Silkworm gut was left for permanent drainage. The patient collapsed and died. The speaker questioned whether such operations were justifiable.

Dr. Rotch, who spoke from considerable experience, declared the operation in itself to be simple and free from danger. A little fluid should be withdrawn daily. The results were invariably bad, as the operation was in no way curative. Lumbar puncture was no better.

Dr. Dorning mentioned a child aged nine months from whom two ounces of fluid was drawn by lumbar puncture. The convulsions ceased and the case improved for three weeks, when it passed from observation.

Dr. Koplik spoke of three cases of chronic hydrocephalus, one child being two years old, whose anterior fontanelle was drained. It did well for a time, but died with stupor and convulsions. In a case of a child seven months old, with stupid days and nights of crying, it was subjected to lumbar puncture. From 10 to 20 c.c. of fluid was removed weekly for six weeks. The temperature then rose to 108° F., a peculiar rash appeared, and the child died in convulsions. Infection was suggested, but could not be proven, as great care and antisepsis had been maintained. No tubercles were found at the autopsy.

Dr. Davis preferred direct drainage to puncture. In one of his cases the child had a head increasing in size notwithstanding the puncture.

The Nephritis of Influenza in Children.—Dr. Rowland G. Freeman, of New York, read this paper. He said that nephritis was among the rarer organic lesions in childhood. In most cases with high temperature there was albumin in the urine, but real nephritis rarely occurred. Minor mentions four hundred cases of influenza with only one per cent. of nephritis as a complication. In 55,263 cases in the German army, only ten patients were noted as having nephritis. In Lichtenstein's four hundred cases there were but two with complicating nephritis. The complication was more common in children than in adults. The literature supplied only seventeen legitimate cases in both adults and children. Five occurred under the age of twelve years. Only two of twelve patients died. The prevailing type was the acute hemorrhagic. The urine was diminished; blood and albumin were present. His case was that of a boy aged four years who had influenza each winter. The temperature was 102.5° F. The urine was normal on the fifth day, red on the sixth, scanty and full of blood on the ninth; casts and epithelium were present. In ten days it was again normal. The patient passed thirty ounces daily for weeks, usually of low specific gravity, but on one occasion 1.050. The child recovered, as was usual in such cases.

Dr. Fruitnight emphasized the rarity of the affection. He had examined the urine of fifty-seven children with influenza and found albumin in but one.

Dr. Dorning remarked that the condition seemed to be rare, but it would stimulate physicians to more careful analysis in all cases. He cited three cases occurring during the past winter; one in a boy of nine years, with œdema of the face and urine showing thirty per cent. of albumin, with blood and casts; also a child four years old in the same family. A third had smoky urine with fifty per cent. of albumin, and was not yet well. He advocated baths and laxatives with abundance of water.

Dr. Jennings had had but one case, and that followed the double infection of influenza and measles. The child was six years old, and passed urine of 1.015 specific gravity, containing abundant albumin and casts. All cleared up in three days. There was neither dropsy nor languor. The temperature was 102° F. on the second day, but fell rapidly.

Dr. Rotch called attention to the indefiniteness of the symptoms compared to the lesions. It was not so in adults. We had few basal notes for conclusions, but it seemed that interstitial nephritis was usual, while glomerular nephritis was common in scarlatina. The diet should always be carefully regulated in order not to overtax the kidneys, even in simple cases.

Dr. Dorning asked if the amount of albumin determined the variety, to which Dr. Rotch replied that it was not known yet. Pathological findings were not in accord with symptoms.

Dr. Carr cited a case similar to that of Dr. Freeman, except that the patient also had rupture of the ear drum. The child showed a sudden liking for sugar, and the urine reached a specific gravity of 1.040 with abundant sugar, the albumin disappearing. Of fifty cases of influenza examined, none presented albumin.

Dr. Churchill, of Chicago, said that physicians did not examine the urine enough, and frequently looked for albumin alone. The infectious diseases of childhood often led to kidney changes that became serious lesions late in life. Renal irritation was common with infectious diseases, and cylindroids then abounded, with a few casts. He mentioned a patient with appendicitis who was found to have chronic parenchymatous nephritis. He had had influenza six months before. When four years old he had had measles and suffered ever since from intestinal troubles. The speaker asked which disease led to the nephritis. Urinary sediments should always be examined.

Dr. Augustus Caillé stated that albumin and blood casts made the clinical diagnosis. The prognosis was always good, as children had wonderful recuperative power in kidney diseases. He instanced a case of a patient, now well, which he had watched twenty years, since nephritis of childhood.

Sudden Death from Perforation of Trachea and Bursting of a Caseous Gland.—Dr. Caillé presented this case. It was that of a girl, four years old, who was sent to the hospital with a diagnosis of bronchitis. She was full of life and energy, running about the ward, when she suddenly complained of pain in the neck, and soon fell over unconscious. A large O'Dwyer tube was introduced, and the trachea was also opened without relief. After death, which shortly occurred, there was found a cold abscess the size of a walnut at the bifurcation of the trachea. Both bronchi were plugged by its contents. Two similar cases had been reported to the New York Pathological Society. The patient had no pain nor fever and only a few râles over the sternum.

Dr. Rotch said he had been endeavoring to get symptoms of bronchial nodes, but could find few recorded. Their presence was serious and modified the prognosis in all cases of cough. No symptomatology was in the literature. They were much more difficult to detect than were mesenteric and cervical glands.

Dr. Freeman noted the similarity between these cases and post-pharyngeal abscess. He had known one in the foundling asylum to rupture low and suffocate the child. He had opened two post-pharyngeal abscesses, but the patients died later.

Dr. Blackader said there were in these cases a characteristic lack of expansion and slight recession at the bases of the lungs on deep breathing. A case he had seen with symptoms of slight bronchitis had such marked recession that large bronchial glands were diagnosed. The upper superficial veins were distended. Large nodes interfered with the entrance of air, causing slight cyanosis.

Dr. Fruitnight considered elevation of the chin to the horizontal line absolutely useless so far as producing a characteristic murmur was concerned.

Dr. West reported several cases, and declared that the murmurs could be brought out. Three cases showed clear murmurs that disappeared as the glands subsided, but reappeared as the glands again enlarged. Four showed weaker respiratory movement on one side. The cough in all resembled whooping-cough.

A Congenital Cardiac Malformation with Endocarditis and Anuria.—Dr. A. C. Cotton, of Chicago, presented this paper and specimen. The child's mother had neither syphilitic nor rheumatic history. The child weighed seven pounds four ounces, and appeared healthy when born, but its respiration was delayed. Pallor and grayness changed finally to cyanosis. The temperature was 102.5° F.; pulse, 160; respiration, 48. Over the heart was a loud, harsh diastolic murmur. No urine was passed; the bladder was empty. On the third day the child nursed, and was not restless or irritable. There was no eclampsia. On the fifth day it died. Numerous subpleural hemorrhages were found, but no bronchitis. The heart was large, especially the left ventricle. The right side was normal. The size of the heart was $4\frac{1}{2}$ by 5 cm.; weight, 42 gm. The foramen ovale was normal. The mitral orifice was small. There were smooth nodules on the chordæ tendineæ. The anterior segment of the valve was held by a band-like bridge. There was a bulging of the wall between the aorta and pulmonary artery as though they had failed to meet. The beginning of the aorta was wider than usual. In the kidneys were uric-acid infarctions. Three hundred cases of fœtal endocarditis showed the left side only affected. Uric acid might be formed from the nuclei of leucocytes, or be present through imperfect oxidation. Both theories added interest to this case.

Dr. Adams asked if the temperature did not indicate a septic endocarditis. He had found only two cases of congenital septic endocarditis in the literature. He considered that there was no direct relation between the anuria and heart condition. Infarcts were common in the kidney, and were usually septic, not due to uric acid. He always used hydrotherapy.

Dr. Cotton mentioned seeing six fatal cases of anuria, even though the books spoke so lightly of it. Four of these patients had anomalous hearts, as seen at the autopsy. Two others were recognized as "blue babies."

Enteric Fever in Childhood.—Dr. A. D. Blackader read this paper. It was a careful analysis of one hundred consecutive cases in private practice and two in hospitals. All were of children under fifteen years of age. Four were of infants under two years old, the youngest thirteen months. This one had early symptoms like incipient meningitis. It had four or five loose stools daily, and died after five days. The Widal reaction was present. The proportion of cases increased regularly in number with the years of age. As the disease was comparatively rare, all continued fevers of remittent type should be carefully investigated. There was no dividing-line where adult and infantile forms differed. Less than fifteen of these cases were mild. The duration averaged three weeks. Eighty-three per cent. of the patients had headache, forty-nine per cent. anorexia; twelve were chilly; thirty-six had loose stools, and ten had real diarrhœa. In only four did this require treatment. Twenty-three had epistaxis. One had a convulsion, but it was attributed to food. Several had subnormal temperature, one having a rectal temperature of 95° F. for four days. Thirty-seven had temperatures of 104° F. or over. Fifty-five had rose spots. Four had bloody stools. As a rule the pulse was slow, showing the effect of toxins on the pneumogastric. Three cases required catheterizing, and five showed albumin in the urine. Widal's reaction was tried in forty-three cases, in three of which it failed. Cold water after Brand was the regular treatment. Strychnine was the heart tonic. The great value of baths was shown as a general and nerve tonic, not as antipyretic alone. The duration and temperature of these baths must be as carefully modified to the case as doses of medicine. Regularity in baths was necessary for definite effect.

Dr. Cotton inquired whether laxatives were given for constipation. He had reported one hundred cases seen in Chicago. The constipated cases usually had a high temperature, which fell after an enema of glycerin and oil.

Dr. Adams said there was no doubt of enteric fever occurring in patients under one year of age. He had seen them typical at one year. Twice he had seen insanity follow typhoid in children. The child should be put in a bath if necessary. It was harmful to put a child in a bath of very low temperature; 90° F. was enough. He cited a case of a patient who lived on ice-cream.

Dr. Northrup maintained that it was proven that children under two years of age were little susceptible to typhoid. They might acquire it surely, as did a seven months baby, the sixth case in one family, or another infant who was fed milk by and with its sick father. Typhoid was not an infants' disease. It was hard to detect. If they really had it, all symptoms were clear, more so than in adults. Large intestinal follicles did not indicate typhoid. Most of the doubtful cases were of entero-colitis. The child should be cooled with water inside and out, but the feet must be kept hot. Ice-cream might be given, as it was only iced cornstarch.

Dr. Griffith remarked that too much typhoid was seen in Philadelphia. It was "the physician's privilege but the city's disgrace." As diarrhœa was not common he thought the previous speaker's statements were illogical. Typhoid was difficult to recognize because many symptoms were so often lacking, but now the Widal reaction made the diagnosis sure. He had seen cases in children aged seven months and three months. All were liable, but still it was rare in the very young. Children did not bear water so well as adults; it should not be of lower temperature than 85° F. Warm bathing was good and should be revived.

Dr. Rotch said all evidence pointed to the possibility of the occurrence of typhoid; but why emphasize it? Young and old were affected alike, but the young in a less pronounced manner. Rose spots were more common in the young. Cold baths were not necessary. If the child was wrapped in wet gauze and fanned, it would lower the temperature.

Dr. Wilson declared that no single series of cases could settle treatment. There could be no question that infancy did carry a certain immunity, because few were liable to exposure. There were two types of typhoid in adult and child, and the two were often reversed. In infancy there were not all the clinical criteria. Most cases were mild, and hence the prognosis was good. Baths must be used systematically, but modified from the original Brand method. The treatment should begin with a bath of 90° F., and each three hours followed by one a little lower. The child should be kept in only eight or ten minutes, and soon came to like it. The bath was not essentially an antipyretic. Its regular use modified the nervous symptoms, secretions, excretions, and general nutrition. Very cold water was not needed, as there was danger of over chilling. The superficial area of a child was great in proportion to its resistance. The adult was helped by the cold shock, but not so the infant.

Dr. Fruitnight cited a case of intercurrent measles and typhoid. The measles developed about the twentieth day with a temperature of 105° F., delirium, and prostration.

Dr. Freeman stated that milk epidemics of typhoid should show many cases in children, as they were more likely to drink it.

Dr. Miller commented on the lack of autopsies.

Dr. Dorning reported three cases in children under a year old. All came to autopsy and presented the shaven-beard appearance of Peyer's patches, which was thought characteristic. Physicians should use water more freely and learn how powerful it was both for good and for harm. The individual power to react should be considered. Hot and cold were only comparative terms. If one went in a hot-air chamber at 170° F., and had water at 110° F. poured on one's self, it would seem like ice. Discrimination must be had with baths, and friction to the surface should be always employed. He mentioned three patients who took solid diet without ill results, and seemed to regain health most rapidly.

Dr. Northrup reported that he had made two thousand autopsies on foundlings under two years old, eleven hundred being those boarded outside of the hospital. None had shown typhoid lesions. He wished to encourage a healthy scepticism as to its occurrence in children under the age of two years.

Dr. Blackader, in summing up, said that each case demanded its own treatment. Warm baths had no tonic effect, nor did sponging, their only result being antipyretic.

Third Day—Thursday, May 3d.

A Case of Rhachischisis.—Dr. T. M. Rotch, of Boston, read this paper. The case was that of a girl three days old. The head was enormous and delivery was accomplished by forceps. The child was viable. There was marked caput succedaneum. The occiput rested on the spine of the upper dorsal vertebra, the front of the neck bulging forward. There existed a cleft an inch and a half long in the laminæ of the vertebræ. The extremities were normal, also the eyes. The child could not swallow. Rhachischisis often occurred with spina bifida; not so here. When the rhachischisis was total it was often combined with anencephalus. Any region might be affected, perhaps two spots, each including four or five vertebræ. It was caused by the two portions of cord failing to unite in the early development. In this case the viscera were normal.

A Fatal Post-Otitic Cerebral Abscess with Amnesic Aphasia.—This paper was read by Dr. J. Henry Fruitnight, of New York. He said this case well illustrated that the extent and gravity of lesions were not always indicated by grave symptoms. The laity should therefore be educated to the gravity of chronic ear troubles, as physicians should themselves be instructed. In this case the child was twelve years old. It had otalgia and later otitis media, followed by an abscess. The pus was let out. The child was neglected by the mother, who considered the trouble only a running ear. After the pus had been discharging eighteen months, an acute otitis occurred. The vomiting, temperature (100° F.), headache, and prostration pointed to mastoid abscess. Operation was refused. After convulsions set in, operation was allowed and performed by Dr. Herman Knapp. The eyes were found normal, and sensibility was normal. There was no tenderness over the mastoid bone. Word blindness was marked. Epidural meningitis was suspected. The bone was opened and the attic laid bare; all caries was chiselled away. There was no external pachymeningitis. Both the middle and posterior fossæ were opened. A black spot on the dura showed where the abscess lay. In three days there was no word blindness; the next day there was failure on some words; a day later the patient jumped out of bed and died suddenly. The third ventricle and left lateral ventricle contained much pus, with a zone of softening in the brain around. The abscess was in the middle temporo-sphenoidal lobe, and had perforated in two places. The symptoms had indicated meningitis from the beginning, with no characteristics of abscess until the last twenty-four hours. The thick capsule showed that the abscess had been of long standing.

Dr. Herman Knapp said that the case was remarkable and instructive because it was rare to be able to make a certain diagnosis of abscess, and more rare to locate it. Word blindness was located in the lower end of the anterior gyrus, but that was healthy. In the roof of the tympanum was a dark spot 3 mm. in diameter, a certain proof of an abscess. One case occurred, having an abscess wall two lines in thickness, which an aspirator needle would not pierce. Thrombosis was more frequent than these cases, and meningitis still more frequent. The speaker cited a case of right hemianopsia with optic neuritis following long suppuration from the ear, in which the diagnosis was made, the abscess located and operated upon with success. This was the only one in which the scientific inferences were correct throughout. The lesson in prophylaxis was that otorrhœa should never be left alone; caries will later produce mischief.

Dr. H. D. Chapin said that there was a type of mastoid disease in which the brain was not affected, the pus burrowing in front of the ear. He mentioned a case with tenderness behind the ears, but no swelling, all of which was relieved by incising the drums.

Dr. W. P. Northrup spoke of a case with pronounced opisthotonos as a beginning symptom. Pneumonia was suspected, there having been no discharge from the ear. All symptoms were relieved by an operation.

Measurements of Chicago School Children.—This paper was read by Dr. W. S. Christopher. The work had been done during the past year and embraced fifty-six hundred observations. Height and weight were taken in the usual manner, the weight of the clothes being found to be 5.8 per cent. of the total weight. The grip was determined by a special but accurate dynamometer, which was shown. Vital capacity was reckoned equal to the amount of air expired in the spirometer. Hearing was measured by an electrical apparatus. Fatigue and endurance were measured on an apparatus in which the middle finger of the right hand raised seven per cent. of the body weight every second for a minute and a half. The high-school pupils from comfortable homes presented better records than the school whose pupils were of mixed nationality and inferior housing. The energy as recorded on the ergograph showed increasing power of endurance steadily from the age of six years to twenty, except for a year or two at puberty. Another ergographic record showed graphically that endurance fell from ten to twelve o'clock daily and also from the second hour of the afternoon session. The first hour of each session was much the best. This demonstrated the necessity and advantage of dividing the sessions by long intermissions. A nervous child with chorea worked the ergograph for three minutes without apparent fatigue, and only stopped because the record sheet was exhausted. As this was double what could be done by a man in health, some interesting inferences might be made on nerve versus muscle strength. Other experiments were quoted showing that the energy developed by voluntary effort and that by electrical stimulation were the same. It was found that the best mental development went with the best physical development, low mentality being accompanied by low stature. All the various physical conditions followed similar lines in the charts. The extremes of stature in some grades, though few, showed the necessity of each room being fitted with some adjustable desks.

Endurance was naturally found to increase with years, the greatest elasticity being in the upper grades. Vision was counted imperfect at $\frac{20}{30}$. At six years there were few damaged. At twelve years thirty-six per cent. were defective, but at fourteen only twenty-three per cent. were so found, vision seeming to improve with the increasing development at that period. School life therefore did not continuously impair sight. In considering backward children, we must look to the brain or cord, and the motor tracts. The existing defects were caused by (*a*) heredity, (*b*) nutrition, (*c*) infection, and (*d*) trauma. To remedy the evils as well as study conditions required the close conference and discussion of pedagogue, physician, and psychologist.
